The most relevant phosphorus isotopes for the study of soil systems are ^{31}P, ^{32}P, and ^{33}P. Both ^{32}P and ^{33}P are radioactive, ^{32}P and ^{33}P have a short half-life (14.3 days for ^{32}P and 25.3 days for ^{33}P) and emit β^- radiation with a maximum of 0.25 and 1.71 MeV for ^{33}P and ^{32}P, respectively (Endt, 1990).

Labeling the soil solution with carrier-free radioactive orthophosphate ($^{32}PO_4^{3-}$ or $^{33}PO_4^{3-}$) at steady-state equilibrium for $^{31}PO_4^{3-}$ in solution, in the absence of carbon input, allows quantification of the amount of orthophosphate located on the solid phase that can be released into the solution over time, through isotopic exchange. The amount of isotopically exchangeable orthophosphate measured in a soil/solution system is called the E value. The study of the kinetics of isotopic exchange shows that most of the soil inorganic phosphate must be seen as isotopically exchangeable, but some ions (a few) appear very rapidly in the solution whereas other ions (the large majority) need a lot of time to be released into the soil solution (Frossard and Sinaj, 1997). The analysis of the specific activity (e.g., $^{33}PO_4^{3-}/^{31}PO_4^{3-}$) in the fractions of a sequential extraction gives information on the isotopic exchangeability of the phosphate present in the different fractions (Bühler et al., 2002).

The principle of isotopic exchange can be used to assess the basal mineralization of soil organic phosphorus. In biologically active soils that have been labeled with radioactive orthophosphate, the decrease of specific activity of orthophosphate in the soil solution can be related to the release of nonradioactive orthophosphate ($^{31}PO_4^{3-}$) to the solution through isotopic exchange and to the mineralization of $^{31}PO_4^{3-}$ from soil organic matter (Bünemann et al., 2007). Once the appropriate controls have been prepared to quantify the amount of $^{31}PO_4^{3-}$ released by isotopic exchange, it becomes possible to deduce the amount of phosphorus mineralized from soil organic matter. Furthermore, by measuring the concentration of radioactive phosphorus in the soil microbial biomass, it is possible to assess phosphorus immobilization (Bünemann et al., 2007).

The same principles can be applied to assess whether a growing plant can solubilize significant amounts of slowly exchangeable phosphorus to cover its needs. To do this, the fraction of soil phosphorus that is isotopically exchangeable within a given time is measured in a soil/solution system (E value) and compared to the amount of isotopically exchangeable phosphate measured over the same period with a plant growing in a labeled soil (L value). If L is higher than E, and provided that the pitfalls of both methods have been avoided (Pypers et al., 2006), then it can be concluded that the plant had access to a fraction of phosphorus that was initially not isotopically exchangeable, for example, through the root exudation of organic acids or phosphatase.

Finally, the use of phosphorus added as mineral or organic fertilizer by plants can be assessed either directly, when the fertilizer is homogeneously labeled with radioactive phosphate or, when the fertilizer cannot be homogeneously labeled by radioactive phosphate, indirectly by labeling soil-available phosphate with radioactive phosphate (Gallet et al., 2003).

The most relevant sulfur isotopes for the study of soils are ^{32}S and ^{34}S, which are both stable and ^{35}S, which is radioactive. About 95% of the total sulfur is present as ^{32}S while ^{34}S represents 4.21% of total sulfur.

The fate of sulfur in the environment can be studied using fertilizers enriched in ^{34}S or by measuring the natural abundance of ^{34}S ($\delta^{34}S$) in different sulfur forms. Knöller et al. (2005) showed by measuring $\delta^{34}S$ in sulfide and in sulfate from soils and groundwater and the natural abundance of ^{18}O ($\delta^{18}O$) in sulfate, that sulfate in water in a catchment located in eastern Germany was mostly derived from past and actual anthropogenic sulfur inputs (i.e., from the atmosphere and fertilizers) and in more restricted areas from the oxidation of sulfide. They also suggested that mineralization of C–S compounds from soil organic matter had released significant amounts of sulfur to groundwater.

Dissimilatory sulfate reduction, which is mediated by a number of enzymatic steps, strongly fractionates sulfur, with the lighter isotope being preferentially reduced, whereas sulfur isotopes are almost not fractionated during the biotic oxidation of sulfide to sulfate. Therefore, the $\delta^{34}S$ of sulfate in solution can give information on the activity of sulfate-reducing bacteria (Brunner et al., 2005). Finally, the $\delta^{18}O$ of sulfate gives information on the transfer of oxygen between water and sulfate molecules under oxidizing and reducing conditions (Brunner et al., 2005; Balci et al., 2007).

The half-life of ^{35}S is 87.5 days and this isotope emits a low-energy β^- radiation (maximum 0.17 MeV) (Endt, 1990). The fate of sulfur added to a soil/plant system in a mineral or organic compound can be directly assessed when the compound can be homogeneously labeled with ^{35}S (Vong et al., 2007). Immobilization and mineralization fluxes of sulfur in soils can be studied by labeling the soil with $^{35}SO_4^{2-}$ (Knights et al., 2001). Nziguheba et al. (2005) improved the isotope dilution method to assess sulfur immobilization by simultaneously taking into account the changes in radioactive and nonradioactive sulfate in KH_2PO_4 extracts during soil incubation. This approach gives a more precise evaluation of immobilization and therefore of net mineralization. In a further step, Nziguheba et al. (2006) extended their isotopic dilution approach to assess the mineralization and immobilization of sulfur induced by the addition of nonlabeled plant residues. In these studies, the authors obtained L values measured with Italian ryegrass that were similar to

the *E* values measured in soil/water suspensions and came to the conclusion that Italian ryegrass had very little access to nonlabeled sulfur forms.

26.1.2.4 Molecular Biology Tools for the Study of the Phosphorus and Sulfur Cycles

Molecular methods have allowed identification of changes in composition and diversity of microbial communities in response to changes in size of soil phosphorus pools and phosphate availability as achieved, for example, by different fertilization regimes (He et al., 2008; Cruz et al., 2009).

The advantage of these (mostly DNA-based) tools is mainly in their capacity to cover a broad range of both culturable and unculturable microbes, with the latter usually vastly dominating the microbial community in most soils. Sequencing of excised bands from molecular profiling gels and novel low-cost and high-throughput environmental sequencing tools (Cardenas and Tiedje) could potentially reveal the identity and abundance of microbes that specifically occur in environments with contrasting levels of available phosphate. In spite of the current technology-driven boom in metagenomics and molecular profiling tools, the DNA-based methods can provide only limited insight into the processes in phosphorus cycling, because of our limited understanding of linkages between microbial identities and functions. For example, not all members of a given taxonomic group have the same metabolic capabilities and not all microbes possessing genes for a particular metabolic pathway such as phytate degradation necessarily express the metabolic activity under all circumstances. Thus, in order to confirm the capacity of certain microbes to access certain phosphorus sources and to study the mechanisms and kinetics of the associated metabolic pathways such as release of organic acids, protons, cyanide, enzymes, and chelates (Welch et al., 2002; Chen et al., 2006; Uroz et al., 2007; Jorquera et al., 2008), it is still essential to cultivate the microbes themselves or to use transgenic organisms that express relevant genes from uncultivated organisms. Furthermore, DNA from dead cells is stable in some soils for a certain period of time (Pietramellara et al., 2009), and this may bias some of the methods based on soil DNA extractions.

These concerns have stimulated recent developments in RNA-based approaches, which offer complementary information to the analyses of phylogenetic affiliations within microbial communities and which are more directly relevant to metabolic processes than the DNA-based methods (Yergeau et al., 2009). For example, the activities of certain metabolic pathways such as cellulose degradation and N_2 fixation were shown to correlate with latitude and environmental properties along a soil transect across Antarctica, using functional gene microarray technology (Yergeau et al., 2007). Similar comprehensive studies focusing on genes related to phosphorus cycling have yet to be completed. The concepts emerging from the descriptive studies can be further scrutinized by using genetically engineered microorganisms or plants (over) expressing certain metabolic pathways (George et al., 2005).

Coupling this approach with in situ quantification of the pool sizes and reaction rates of soil enzymes, using molecular biology, proteomics, and other tools, should eventually allow mechanistic modeling of the processes involved in biological transformations of phosphorus in the soils (Nannipieri, 2006; Wallenstein and Weintraub, 2008).

Molecular methods for the analysis of microbes mediating sulfur transformations in soils have concentrated on those organisms that catalyze the inorganic sulfur cycle, with particular emphasis on sulfate/sulfite-reducing prokaryotes and on sulfur-oxidizing prokaryotes. These two groups of organisms are both taxonomically very diverse, but the members of each group share conserved pathways of sulfur-based metabolism that have allowed the development of DNA-based methods that relate functional gene diversity to taxonomic diversity. A microarray based on 16S rRNA sequences of known sulfate/sulfite-reducing prokaryotes species has been used for a number of years (Loy et al., 2002), and this has been complemented by methods based on specific oligonucleotide primers targeting the dissimilatory sulfite reductase genes (*dsrAB*) (Loy et al., 2004; Wagner et al., 2005; Schmalenberger et al., 2007), including quantification of these organisms with real-time PCR (Stubner, 2004). Polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE) methods using these genes have been developed to evaluate how environmental variation affects sulfate/sulfite-reducing prokaryotes communities (Geets et al., 2006; Miletto et al., 2007) and to examine biogeography and spatial distribution of these organisms (Miletto et al., 2008). Like all DNA methods, these methods yield data on the relative abundance of the organisms concerned, but this does not necessarily reflect their activity in situ, and quantitative environmental studies based on functional RNA are still rare. Sulfur-oxidizing prokaryote diversity in various environmental habitats has also been subjected to molecular analysis, using specific primers targeting the dissimilatory adenosine-5′-phosphosulfate reductase (*aprBA*) and reverse dissimilatory sulfite reductase genes (*dsrAB*) (Meyer and Kuever, 2007a, 2007b; Loy et al., 2009). These genes are present in both sulfate-/sulfite-reducing prokaryotes and sulfur-oxidizing prokaryotes, and so an appropriate choice of primers allows simultaneous diversity analysis (Meyer and Kuever, 2007a), which promises to be a valuable tool in the future.

Molecular approaches for correlation of microbial diversity with changes in sulfur supply are less common than for the corresponding studies with phosphorus, partly because long-term fertilization experiments have seldom controlled for the sulfate levels provided (Kertesz et al., 2007). Molecular methods have been used to analyze organosulfur cycling in one such project, evaluating changes in microbial sulfonatase diversity in sulfate-rich and sulfate-limited rhizospheres using a sulfonatase-related gene (*asfA*) (Schmalenberger and Kertesz, 2007; Schmalenberger et al., 2009). However, the most widely used marker of organosulfur cycling in soils is the arylsulfatase enzyme, and molecular studies of the diversity and expression of sulfatase genes in the soil have not yet been reported.

26.1.3 Biotic Processes

26.1.3.1 Uptake of Phosphorus and Sulfur by Plants

Plants take up orthophosphate from the soil solution through root hairs and mycorrhizal symbionts. The amount of phosphate present in the soil solution at a given time is far lower than the total plant need. When a plant takes up phosphate, a phosphate-depleted zone appears along the root creating a concentration gradient from the soil particles to the root surface triggering the diffusion of phosphate from soil particles to the surface of the root.

Since phosphate ions cannot diffuse over long distances in the soil, root morphology, root hairs, and the presence of mycorrhizal symbionts are determinants for phosphate uptake. Some plant species can increase the rate of phosphate solubilization in their rhizosphere through the exudation of protons, organic acids, and phosphatases (Hinsinger, 2001; Turner, 2008). Protons dissolve calcium-bound phosphate, organic acids chelate cations bound to phosphate and phosphatases release phosphate from mono- and diester-P. White lupin is known for being extremely efficient in solubilizing scarcely soluble phosphate forms and for efficient phosphate uptake through its cluster roots (Neumann et al., 1999). *Brassicaceae* are also efficient in using scarcely soluble mineral phosphate compounds (Marschner et al., 2007).

Most plant species, however, do not exhibit such adaptations and rely on the symbiosis they establish with mycorrhizal fungi for phosphate uptake. Thanks to their extra-radical hyphae these fungi are able to take up phosphate from a volume of soil that is much larger than that explored by the roots. Phosphate is then transported to the plant and in exchange the plant provides reduced carbon to the fungus. Arbuscular mycorrhizal fungi are the most widespread; they form a symbiosis with 80% of higher plant species and are particularly important for crop plants (Jansa et al., 2006). They have a high level of functional diversity and are influenced by agricultural management practices (Jansa et al., 2006).

A number of phosphate transporters have been identified in AMF hyphae, in the plant for uploading phosphate from AMF arbuscule, in root hairs for uploading phosphate from the soil solution, for up- and downloading phosphate in the xylem and phloem, and for phosphate transfer within plant cells (Bucher, 2007). The expression of genes coding for some of these transporters (e.g., on root hairs) is upregulated when the phosphate concentration in the soil solution decreases.

Most of the sulfur in plants is taken up by roots as sulfate from the soil solution. Plants can also take up sulfur dioxide through their stomata when sulfur inputs from the atmosphere are high (Kertesz et al., 2007). Since plants can release and take up amino acids through roots, they are probably also able to take up sulfur-containing amino acids (Kertesz et al., 2007). A series of sulfate transporters and amino acid transporters have been identified for their uptake in the roots, for the uploading and downloading from the xylem and phloem, and for sulfur distribution within cells.

The role of mycorrhizal fungi on sulfur uptake by plants is not well understood. Mycorrhized plants appear to take up more sulfur than non-mycorrhized plants. Kertesz et al. (2007) hypothesize that this higher uptake could be due to the association of soil bacteria that would release sulfur to the solution, which would then be taken up by mycorrhizal hyphae. Once in the plant, sulfate is reduced and incorporated in methionine and cysteine, which are then incorporated in proteins. *Brassicaceae* and *Alliaceae* also use a large fraction of their sulfur for the production of secondary metabolites.

26.1.3.2 Role of Soil Microorganisms in the Phosphorus Cycle

Soil microorganisms can affect nutrient speciation and at the same time act as a source or sink for nutrients (Oberson and Joner, 2005). Many soil microorganisms can solubilize calcium, iron, and aluminum phosphate minerals under laboratory conditions. Under these conditions, acidification of the medium and release of various organic acids were shown to be the main mechanisms through which microorganisms could solubilize calcium phosphate compounds (Gyaneshwar et al., 2002).

Gyaneshwar et al. (2002) report however the limited effects on crop phosphate nutrition of these solubilizing microorganisms when applied in the field. These limited effects can be explained by the high buffer capacity of calcium phosphate-rich soils (generally calcareous soils) leading to a rapid disappearance of the protons released by the microorganisms (Gyaneshwar et al., 2002), by the rapid degradation of organic acids by soil microorganisms (Jones and Darrah, 1994), and/or by the growing conditions of the microorganisms in the rhizosphere that are totally different from those used in the laboratory to assess phosphate solubilization rates.

Microorganisms can develop other strategies to release phosphate from scarcely soluble minerals. Hamdali et al. (2008) show that actinomycetes isolated from Moroccan rock phosphates solubilize calcium phosphate through the production of siderophores and not organic acids. Hoberg et al. (2005) show that an actinomycete (*Gordonia* sp.) and a bacterium (*Pseudomonas fluorescens*) access phosphate sorbed on the surface of a goethite through different mechanisms. *Gordonia* sp. increases the pH of the solution, which increases the density of negative charges of the oxide surface, resulting in phosphate desorption, while *P. fluorescens* exudes citrate and decreases the pH of the solution leading to a probable dissolution of the goethite surface and to a release of phosphate.

Soil microorganisms produce extracellular phosphatases to hydrolyze esters P to phosphate. Fungal and bacterial phosphatases (phytases, acid phosphatases, and alkaline phosphatases) have been characterized, and their genes cloned and expressed in various microorganisms (Wyss et al., 1999; Moura et al., 2001). A gene encoding a protein that regulates phosphorus metabolism (phosphorus starvation response *psr1*) has been described in the green alga *Chlamydomonas reinhardtii* (Wykoff et al., 1999). It is hypothesized that during a period of phosphate starvation, the protein PSR1 is activated

and temporally regulates the transcription of specific genes encoding, for example, the production and excretion of alkaline phosphatases in the extracellular medium (Wykoff et al., 1999). Tarafdar et al. (2002) showed a strong linear relationship between the intra- versus extracellular alkaline and acid phosphatases and phytase activity in six soil fungi. About 25% of the acid and alkaline phosphatases activity was observed outside of the cell, while more than 90% of the phytase activity was observed in the extracellular medium.

Finally, some microorganisms (*Pseudomonas* sp., *Enterobacter* sp., and *Pantoea* sp.) have the capacity both to solubilize calcium phosphates and to hydrolyze phytate and other organic P (Jorquera et al., 2008). Gyaneshwar et al. (2002) consider however that more work is needed on the mechanisms and the genetics of phosphate solubilization by soil microorganisms before these can be used to efficiently improve crop nutrition.

Once released in the solution, phosphate can be taken up by microorganisms to cover their needs and either be remineralized or stored in organic forms for longer periods. The amount of phosphate stored in the microbial biomass as measured by fumigation–extraction techniques ranges between 1% and 10% of total P in the upper horizon of cropped and grassland soils, and reaches higher values in forest soils.

Microbial phosphate content is determined by the total microbial biomass and its activity, which in turn is controlled by the soil organic matter content and organic matter inputs (Oberson and Joner, 2005). Bünemann et al. (2008) used liquid-state ^{31}P NMR to characterize the forms of phosphorus stored in bacteria and fungi isolated from two soils. They observed mono- and diester phosphates in bacteria and fungi, but the concentrations of these phosphate species were higher in bacteria. They also observed higher concentrations of pyro- and polyphosphate in fungi. Finally, they showed that the forms of phosphorus observed in fungi and bacteria were similar to those observed in NaOH–EDTA soil extracts.

When microbial growth is favored, for example, following the addition of organic substances, or when phosphate availability is very limited, microorganisms tend to accumulate phosphorus without releasing it to plants (Bünemann et al., 2004). Phosphate release then occurs following strong changes in the microenvironment, such as drying/rewetting or freezing/thawing cycles (Turner and Haygarth, 2001), or following predation, for example, by protozoa, nematodes or amoebae. Microbial phosphorus and soil organic phosphorus can be remineralized either following the death of microorganisms or through the action of extracellular enzymes as described above.

Soil organic phosphorus mineralization has not been studied extensively because of methodological difficulties. The rate of organic phosphorus mineralization is linked to soil biological activity (Oehl et al., 2004) and most probably also to the microbial community structure and to the organic phosphorus content and forms. The application of exogenous organic matter can increase or decrease phosphate release to the solution depending on its quality. Ha et al. (2007) observed that residues of flowering pea with a low C/P led to a strong release of phosphate while residues of mature pea with a very high C/P ratio led to phosphate immobilization by microorganisms.

26.1.3.3 Role of Soil Microorganisms in the Sulfur Cycle

Soil microorganisms can affect sulfur forms and availability in four ways: (1) through oxidation, when reduced sulfur is used as an electron donor for respiration; (2) through reduction when oxidized sulfur is used as a terminal electron acceptor; (3) through immobilization when inorganic sulfur is taken up by microorganisms to build proteins and structural cell components; and (4) through mineralization when microbial sulfur is released as inorganic sulfur to the soil solution (Siciliano and Germida, 2005).

Many soil bacteria are able to use sulfur as a source of energy by oxidizing elemental sulfur (S°) to sulfite and sulfate using O_2 or nitrate as final electron acceptors. It is assumed that *Thiobacillus* sp. dominate when energy and organic matter are limited and when dissolved reduced sulfur compounds are present in high concentrations. In soils rich in organic matter, when levels of reduced sulfur compounds are low, sulfur oxidation is carried out by heterotrophs (Siciliano and Germida, 2005).

Sulfate-reducing bacteria are found in highly anaerobic environments. They oxidize organic compounds (lactate, pyruvate, and acetate) or hydrogen as electron donors, and use the enzymes adenosine-5′-phosphosulfate reductase and dissimilatory sulfite reductase to transfer electrons to adenosine-5′-phosphosulfate and sulfite leading to the production of hydrogen sulfide that precipitates in the presence of metals.

Finally, some bacteria with phylogenetic affiliation to the sulfate-reducing bacteria can also disproportionate sulfur (Finster, 2008). Such bacteria can for instance oxidize one sulfur atom of thiosulfate to sulfate while simultaneously reducing the other sulfur atom to hydrogen sulfide (Equation 26.1):

$$S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+ \qquad (26.1)$$
Like plants, soil microorganisms take up sulfate from the solution through transporters, reduce it to sulfite, and incorporate it into cysteine and methionine and then into proteins. When sulfate has been exhausted, some microorganisms take up sulfonates and transform them into sulfite to cover their sulfur needs. The genetic control and the transformation pathways of sulfonate assimilation by bacteria have been studied extensively. Three gene clusters seem important: the *ats* gene cluster, which is responsible for the binding of aromatic sulfonate, the *ssu* gene cluster, which controls the cleavage of the C–S bond, and the *asf* gene cluster, which provides reducing equivalents (Siciliano and Germida, 2005; Kertesz et al., 2007).

The use of sulfonate by bacteria is a very relevant phenomenon as (1) during plant growth, sulfate gets depleted along plant roots, (2) sulfonates make up an important fraction of organic S in aerobic soils, and (3) plants are not able to use sulfonates (Kertesz et al., 2007). The principle rhizosphere genera able to desulfurize sulfonates belong to the β-proteobacteria (e.g., *Variovorax*, *Acidovorax*, and *Polaromonas* strains) and actinobacteria

(mostly *Rhodococcus* strains) (Kertesz et al., 2007). However, given the complex environment of sulfonate molecules in the soil, these bacteria or other rhizosphere organisms must be able to extract sulfonate from the soil matrix and make it available to the bacteria. These mechanisms remain to be discovered. Once the needs of the microorganisms for sulfur are covered, they downregulate the genes controlling the use of sulfonate. Kertesz et al. (2007) suggest that through predation of these bacteria by, for example, protozoa, sulfur contained in these bacteria could be released into the soil solution and become available to the plant.

In response to sulfate deficiency, soil microorganisms can also produce arylsulfatase enzymes that release sulfate from sulfate ester, but little is known about the microorganisms producing these enzymes. Work done by Vong et al. (2007) suggests that the release of carbon and nitrogen from roots increases microbial immobilization of sulfur and sulfate mineralization, and that sulfate net mineralization is much more important in the rhizosphere of oilseed rape than in the rhizosphere of barley. They showed furthermore that arylsulfatase activity was higher in the rhizosphere soil of oilseed rape. These results complement those obtained by Dedourge et al. (2004) showing that the application of glucose and of model "rhizodeposits" to soils result in sulfur immobilization and that the increase in intra- and extracellular microbial arylsulfatase activity is positively related to the amount of immobilized sulfur. Altogether these results suggest that the dynamics of sulfur in the rhizosphere is mediated by microorganisms using rhizodeposits as carbon source.

Once sulfate has been released into the soil, it can be taken up again by microorganisms and stored in different organic forms or be remineralized. Soil microbial sulfur as measured by the fumigation technique ranges between 1% and 3% of total soil S (Zhao et al., 1996). A case study showing the relationships between microbial activity and sulfur dynamics as affected by land use and fertilization is presented in Section 26.1.4.2.

26.1.3.4 Role of Soil Macrofauna in the Phosphorus and Sulfur Cycles

The soil macrofauna (earthworms, termites, ants, etc.) affects nutrient cycling through decomposition of organic residues and through effects on the spatial distribution and accessibility of nutrients in the soil. Since most work has concentrated on the role of earthworms in phosphorus dynamics, the following section will focus on that aspect.

Earthworms create structures that represent habitats with characteristics different from the surrounding soil (Decaens et al., 2002). Plant-available phosphate concentrations are usually higher in earthworm casts (Jiménez et al., 2003; Chapuis-Lardy et al., 2009) and in burrow walls (Tiunov et al., 2001). Under field conditions where earthworms ingest soil plus organic residues, total phosphorus concentrations are higher in casts than in surrounding soil (Jiménez et al., 2003). This increase is distributed over all inorganic and organic phosphorus fractions, including microbial phosphorus. Thus, particularly under phosphate-deficient conditions, earthworm casts present spots with clearly increased phosphate availability for plants. Ouedraogo et al.

(2005) report that earthworms contribute to the solubilization of rock phosphate.

However, negative impacts of earthworms on P cycling have also been reported. The invasion of north temperate forests by exotic species of earthworms resulted in the loss of the forest litter, which altered the location and nature of nutrient cycling in the soil profile (Suaréz et al., 2004). On cropped land, earthworm surface-casts can increase soil erosion and particulate transfer if the casts become detached from the soil matrix (Le Bayon et al., 2002). Thus, earthworm surface-casts can contribute to the loss of organic matter and phosphorus from soils because of the selective ingestion of the finest particles and organic material by earthworms and the resulting higher cast phosphorus concentration.

Complex trophic interactions exist between soil macrofauna (e.g., earthworms, termites, and diplopods), mesofauna (mainly microarthropods such as collembola, acarids, and enchytraeids), microfauna (nematodes and protozoa), and microflora (bacteria and fungi) (Cortet et al., 2003; Thies and Grossman, 2006). Microbial biomass, basal respiration, microbial volume, and abundance of protozoa are greater in *Lumbricus terrestris* burrow walls than in surrounding control soil (Tiunov et al., 2001), showing that several groups of organisms affect phosphate availability in the microhabitats created by earthworms.

Land use has a strong impact on macrofaunal communities (Decaens et al., 2004). The conversion of tropical forests or native savanna to agropastoral systems resulted in a sharp decrease in the volume of biostructures created by earthworms and ants when an annual crop was introduced (Decaens et al., 2002) or after slashing and burning (Decaens et al., 2004). As soils of these systems are often phosphate limited, this decrease represents a loss of niches with higher phosphate availability for plants. In contrast, the density of macrofauna and facultative phytophagous, bacterial feeding and predatory nematodes in soils under maize–legume rotations are higher than in maize-monocropped soils, and this promotes soil structure and nutrient availability (Blanchart et al., 2006). In agroforestry systems established on savanna soils, organic fertilization increased earthworm abundance (Lopez-Hernandez et al., 2004). Macroorganisms play a dominant role in the initial phase of manure decomposition (Esse et al., 2001).

While the role of the soil fauna in the cycling of phosphorus is acknowledged, the role of the fauna in the cycling of sulfur remains largely unknown and needs to be investigated.

26.1.4 Case Studies: Phosphorus and Sulfur Cycling in Two Exemplary Soil Systems

26.1.4.1 Phosphorus Forms and Dynamics in the Soil Chronosequence of the Franz Josef Glacier (New Zealand)

The relationships between soil phosphorus and soil development have been studied intensively during the last decades. These studies show that as the soil gets older, total phosphorus stock (expressed in mass of phosphorus per unit of surface) decreases,

the proportion of phosphate bound to calcium decreases, and the proportion of phosphorus bound to organic matter and oxides first increases and then decreases and stabilizes (Walker and Syers, 1976). These studies however relied mostly on sequential extraction schemes for the characterization of soil phosphorus forms and did not consider soil biological activity as a driver of these changes. Work recently conducted in the soil chronosequence of the Franz Josef Glacier located on the West Coast of the South Island of New Zealand has helped to fill this gap (Richardson et al., 2004; Allison et al., 2007; Turner et al., 2007; Doblas-Miranda et al., 2008).

Sites with soil ages varying between 5 and 120,000 years developed on the same parent material (graywacke and schist) were identified along this chronosequence. Strong changes in plant, soil fauna and soil microorganism communities were observed along these sites. Evergreen angiosperms dominated in the younger sites and then decreased while conifers (*Podocarpaceae*), which were absent from the younger sites, appeared in the 500 year old site and became dominant in the 120,000 year old site. Foliar analyses suggested that vegetation became phosphate limited in sites older than 500 years (Richardson et al., 2004). The nitrogen to phosphorus ratio of the leaves of the *Podocarpaceae* found in the older sites indicated that it was less phosphate limited than the evergreen angiosperms. Doblas-Miranda et al. (2008) observed an increase in microbial-feeding nematodes and omnivorous nematodes from the younger site to the 5,000 year old site and then a general decrease of these nematodes till the 120,000 year old site. Interestingly, they observed a dominance of fungal-feeding nematodes in the older sites. Finally, Allison et al. (2007), using phospholipid fatty acid analyses, observed a shift from bacterial to fungal microbial communities from the youngest to the oldest sites. The same authors observed an increase in phosphatase (phosphomonoesterase and phosphodiesterase) activities with increasing soil age and even an increase in phosphatase efficiency (phosphatase activity per unit microbial biomass). Since these increases were correlated with a decrease in soil phosphorus content, these changes in phosphatase activity were interpreted as strategies developed by organisms to scavenge phosphorus in an environment that becomes more and more limiting.

Turner et al. (2007) confirmed the results presented by Walker and Syers (1976) on changes in total P and in P forms, and also conducted a detailed analysis of soil organic phosphorus forms in NaOH–EDTA soil extracts using liquid-state ^{31}P NMR (Figure 26.2). They observed an increase with soil age till 500 years of two isomers of inositol hexaphosphate (phytate and *scyllo*-inositol hexakisphosphate), other monoesters, DNA, phospholipids, phosphonates, pyrophosphate, and orthophosphate. The amount of phosphorus present in these forms then decreased in the older sites. The proportion of extractable organic phosphorus in the form of *myo*-inositol hexakisphosphate decreased after 500 years whereas the proportion of organic phosphorus present as DNA and the proportion of extractable inorganic phosphorus present as pyrophosphate continuously increased with soil age. These results are astonishing as *myo*-inositol hexakisphosphate is thought to be very stable in soils whereas DNA and pyrophosphate are thought to degrade rapidly. The increase in pyrophosphate in the older sites can be linked to the increased presence of fungi as noted by Bünemann et al. (2008) or to the stabilization of pyrophosphate by organic matter (Turner et al., 2007). The increase in DNA could be linked to its stabilization by organic matter (Turner et al., 2007) or on clay minerals. The decrease in *myo*-inositol hexakisphosphate could be related to the decrease in iron and aluminum oxides content. Much remains to be done to understand by which mechanisms phosphorus can be recycled in the older soils where organic phosphorus forms appear to be very stable and available phosphate is very low (Turner et al., 2007). Rhizosphere processes occurring in the root zone of the *Podocarpaceae*, fungal activity, and nutrient recycling through soil fauna might play a determining role (Turner et al., 2007). Although Turner et al. (2007) do not mention them, the mechanisms controlling phosphate release during the very initial steps of soil development would also be interesting to study as this release happens very rapidly.

TABLE 26.1 Percentage Distribution of Organic Sulfur Determined by Sulfur K Edge XANES in Humic Acids Extracts and Sulfur Immobilization and Gross Mineralization Measured in a 53 Day Incubation in the Presence of ^{35}S in Topsoils from the Long-Term Broadbalk Experiment

Soil	Reduced S[a] (%)[b]	Intermediate S[c] (%)[b]	Oxidized S[d] (%)[b]	S Immobilization in Soil (mg S kg[−1])	Gross S Mineralization in Soil (mg S kg[−1])
Woodland since 1882	24.8	46.0	29.1	nd[e]	nd
Grassland since 1882	18.4	37.4	44.3	3.9 (0.20)	6.2 (1.08)
Wheat not fertilized since 1843	14.7	32.8	52.5	3.5 (0.32)	0.9 (0.05)
Wheat fertilized with farmyard manure since 1843	28.7	49.7	21.5	4.5 (0.96)	6.8 (1.26)

Source: Adapted from Zhao, F.J., J. Lehmann, D. Solomon, M.A. Fox, and S.P. McGrath. 2006. Sulphur speciation and turnover in soils: Evidence from sulphur K-edge XANES spectroscopy and isotope dilution studies. Soil Biol. Biochem. 38:1000–1007.

[a] S in a strongly reduced state (e.g., sulfide and thiophene).

[b] Percent of organic S measured using XANES (reduced S + intermediate S + oxidized S = 100%).

[c] S in an intermediate oxidation state (sulfoxide and sulfonate).

[d] S in a strongly oxidized state (ester sulfate).

[e] Not determined.

26.1.4.2 Sulfur Forms and Dynamics in the Broadbalk Long-Term Experiment

Long-term field experiments are essential to assess the effects of agricultural practices and environmental factors on crop yield and soil fertility. The Broadbalk experiment is the world's oldest agricultural field experiment and is extensively described in Poulton et al. (2006). The experiment was set up in 1843 on an Aquic Paleudalf in Rothamsted to the north of London. Its aim was to evaluate the effect of different fertilizations (e.g., no fertilization, full mineral fertilization [NPKS], and farmyard manure) on winter wheat. In 1882, a fraction of the surface under wheat was set aside, and a woodland and a grassland were allowed to develop. Research conducted in this long-term field experiment allowed assessing the effect of sulfur inputs from the atmosphere on the sulfur budget of the soil-crop system, to understand the relationships between land use, fertilization, and sulfur forms in soils, and more recently assessing the effect of fertilization on microbial communities that are important for the mineralization of sulfonates.

Knights et al. (2000) and Zhao et al. (2003) showed that emissions of sulfur to the atmosphere that increased between 1840 and 1970 and then decreased sharply resulted in a significant decrease in δ^{34}S in soil and wheat samples. These results suggest that at the peak of sulfur emissions, 62%–78% of S in the wheat and 28%–37% of S in the top soil of the nonfertilized treatment was derived from sulfur dioxide inputs from the atmosphere. The incorporation of sulfur from atmospheric inputs was higher in the soil that had received manure and on the soils from the woodland and the grassland, leading to an increase in total sulfur content. In treatments that had not received organic matter input in contrast large amounts of sulfur were lost by leaching, resulting in constant total soil sulfur content (Knights et al., 2000).

Zhao et al. (2006) analyzed sulfur speciation by sulfur K edge XANES and the rate of sulfur mineralization and immobilization using a ^{35}S dilution technique approach in the nonfertilized, the NPKS-fertilized, the manure fertilized, the woodland, and the grassland soils. They showed that soils with high organic matter content (woodland, grassland, and manured soils) contained more reduced and intermediate sulfur and less oxidized sulfur than arable soils that did not receive organic matter. Furthermore, the fraction of sulfur released by mineralization was correlated to the fraction of sulfur present in reduced and intermediate forms (Table 26.1).

Finally, Schmalenberger et al. (2008, 2009) identified *Variovorax*, *Polaromonas* (both β-proteobacteria), and *Rhodococcus* (actinobacteria) strains from the rhizosphere of wheat from the Broadbalk experiment able to desulfurize sulfonate. Based on the analysis of DGGE profiles, they showed that the communities of β-proteobacteria and actinobacteria sampled in rhizosphere of wheat were affected by sulfate and manure applications. Analysis of the functional gene *asfA* (oxidoreductase) showed that 40% of the clones belonged to the genus *Variovorax*, that this gene was present in higher number in the rhizosphere soil (where sulfate is depleted) than in the bulk soil, and that higher copy numbers were present in the sulfate-limited soils.

These results suggest that rhizobacteria play an important role in the cycle of sulfur in the rhizosphere and therefore on wheat mineral nutrition, and at a higher level, that land use and organic matter inputs drive sulfur speciation and sulfur immobilization/mineralization in soil.

26.2 Bacterial Transformations of Metals in Soil

Terence L. Marsh

David Long

Thomas Voice

26.2.1 Introduction

Soil ecosystems contain one of the most complex microbial communities on earth. The number of species per gram of soil is controversial (Torsvik et al., 1990, 2002; Dunbar et al., 2002; Torsvik and Ovreas, 2002) but it is certainly large. Each species may interact with metals in different ways. The number of different soil types and the resulting number of possible metal–bacteria complexes result in an interactive matrix of a size well beyond the scope of this chapter. Our objective therefore is to provide an overview of the microbial–metal interactions in soil rather than an exhaustive accounting of all known interactions. Given the physiological diversity of microbes and their ubiquity, they can influence nearly every abiotic process of the metal–soil repertoire through their own habitat-altering metabolic capabilities. In addition, they can reduce or oxidize metals directly through metabolism that can result in habitat alteration at landscape scales. Below we provide a brief description of the fate of metals in soils followed by the microbial processes that alter and transform the state of metals.

26.2.2 Historical Perspective

The work of Winogradsky (e.g., Waksman, 1953) established the concept of chemoautotrophy whereby microorganisms fix CO_2 and obtain energy from inorganic compounds, including metals. During the ensuing years, European microbiologists led the investigations on the "iron bacteria" (e.g., Molisch, 1910), those bacteria capable of oxidizing ferrous. Sixty years of largely anecdotal reports of bacteria capable of precipitating iron followed (see reviews by Pringsheim, 1949; Stokes, 1953) before bacterial iron oxidation was unequivocally linked to growth (Colmer et al., 1950). At around the same time, metal reduction was directly linked to bacterial growth in *Bacillus* (Roberts, 1947; Broomfield, 1954). These observations relating bacterial growth to the valence state and solubility of metals led to new views regarding the deposition of metals in, for example, banded iron formations and bog iron ore. An early monograph by Harder (1919) titled "Iron-depositing bacteria and their geologic relations" suggested the possibility that bacteria played a key role in the formation of Precambrian banded iron formations. A review by Lundgren and Dean (1979) provides a good discussion about early views of this still debated topic. Several viable scenarios have since been put forward that are based on biological activity including oxidation of ferrous by cyanobacteria-produced oxygen (Pierson and Parenteau, 2000) or more recently through direct oxidation by anoxygenic phototrophic bacteria (Klapper

et al., 2005). The origins of bog iron ores are similarly controversial. Early investigators separated marine ferromanganese nodules from freshwater deposits and bog iron ores (Ehrlich et al., 1972). Yet the distinction between lake deposits and bog iron ore was blurred by Arrhenius (1967), who pointed out that landscape succession of shallow lakes developing into vegetation covered bogs linked the deposits found in lakes with bog iron. The origins of bog iron remain a point of discussion with both direct (Gillette, 1961; Chapnick et al., 1982) and indirect (Dean and Ghosh, 1978) microbial activities invoked as well as abiotic scenarios (Varentsov, 1972). These paths of investigation led to a greater appreciation of the metabolic versatility of the bacteria and an increased understanding of their contribution to terrestrial geology.

26.2.3 The State and Fate of Metals in Soils

Metals are natural components of soil and rock minerals, but their presence in soil may also result from anthropogenic activities. Physical, chemical, and biological processes serve to transform and transport metals such that they may be found as precipitates, bound to organic or inorganic surfaces of the soil or colloids in solution, dissolved in the soil solution or in the soil atmosphere (McLean and Bledsoe, 1992). In solution, metals can exist as free cations, but many also form complexes with other organic and inorganic ligands such that the resulting molecule can be cationic, anionic, or neutral (Stumm and Morgan, 1996). The metals themselves may have multiple oxidation states, each of which differ in their ability to form complexes, and the complexes may participate in acid–base reactions (Evangelou, 1998). Both free metals and soluble complexes can form precipitates, either as pure solids, or as mixed solids when multiple metals coprecipitate (McBride, 1994). Soluble metals can also associate with surfaces, or become incorporated into soil components, through a variety of sorption, exchange, and diffusion mechanisms (Sposito, 1989). Precipitation and surface association are generally reversible reactions, with the result that metals can be released back into solution through dissolution, desorption, and exchange, if solution chemistry changes (Sparks, 1995). A few metals, metalloids, and their complexes, notably, Hg, As, Se, and Ra, are sufficiently volatile to be found in the soil atmosphere (Pecheyran et al., 1998). These processes are diagrammed in Figure 26.3.

Understanding the chemical form and soil phase of a metal in the soil environment can be extremely challenging due to the large number of possible reactions. It is theoretically possible to determine the predominate forms by solving a set of equations for the various acid–base, oxidation–reduction, precipitation–dissolution, sorption/ion-exchange and complexation reactions for each of the species in the system using analytical, graphic, or geochemical modeling techniques (Butler, 1998; Langmuir, 1998). These techniques may be limited, however, by the incomplete knowledge of the reacting species and phases, and of equilibrium and kinetic constants associated with the reactions of interest. Particularly problematic in this regard are reactions with organic matter, which are not well characterized chemically
FIGURE 26.3 Processes affecting metal speciation in the soil environment. Uncomplexed metal ions are probably a rare commodity in the aqueous phase with metal complexes predominating and different complexes in equilibrium. Precipitation, sorption, and exchange processes remove metals from solution depositing them in the solid/colloidal phase of soil. Each process can be influenced by microbes through their abilities in (1) providing extracellular organic molecules and specific chelating agents for complexation, (2) binding metal ions to the cell surface and transporting them into the cytoplasm, (3) altering the pH of the local environment through metabolic reactions, (4) reducing or oxidizing metals directly through cell-to-metal contact, and (5) causing precipitation of metallic colloids.

and highly variable such that accurate constants are not generally available (Dudal and Gerard, 2004).

It is within this "dynamic equilibrium in a polyphasic system" (Hopkins, 1913) of metal–soil–solvent that microbes impose their nutritional requirements for metals. Success at this endeavor means that they will grow, metabolize, and evolve. Hence, these are not casual interactions but robust microbial activities aimed at acquiring the necessary metals for growth under conditions of low metal concentrations or detoxifying high metal concentrations, so that growth is possible. Within these two extreme conditions, the diversity of the microbial world has evolved sophisticated approaches to take advantage of metals in soils.

26.2.4 Metals and Microbes

The number of ways that microbes interact with metals is finite and provides an organizational scheme. These interactions are presented graphically in Figure 26.4 and summarized as follows:

- Direct association: Microbes frequently form biofilms and establish microcolonies on surfaces and crevasses of rocks, minerals, and metals. In so doing, these communities actually contribute to the formation of soils by accelerating degradation of parent material. In addition, microbial communities are known to form biofilms and microcolonies on and within soil aggregates as well as on the roots of plants. Thus, the microbial community
FIGURE 26.4 The interactions of microbes with metals. Metals are essential for the structure and function of macromolecules including DNA, RNA, and protein (a). The requirement for metals has led to elaborate systems of homeostasis based on influx and efflux pumps (b). Metals are used as a source of electrons by some populations and as an electron sink by others (c). Microbial cells will actively strip metals from their abiotic environment using excreted siderophores to chelate and transport metals into cells (d). Microbes have also developed techniques to sequester metals. Extracellular sequestration (e and f) locally reduces toxic levels while intracellular sequestration within bacterioferritin (g) allows cells to bank an essential nutrient. Both the expression of fimbriae and flagella (h) can be regulated by metal concentration in the environment, and both may be involved with the formation of biofilm on metal surfaces. Finally, extracellular polysaccharide (i) can bind metals to the surface of cells.

partitions into populations that are either attached to soil particulates and plant surfaces or pelagic within pore water.

- Metals as required nutrients: Metals are required by all known microbes as cofactors for a diverse collection of enzymatically driven reactions as well as an essential component in the folding and conformation of biological macromolecules. Because of these requirements, microbes have developed mechanisms, sometimes elaborate, to recruit metals from the environment. Microbiologically, these processes are described as assimilatory, referring to the assimilation of the substance, in this case metals, into cellular material. Because of the great biological importance of metals, microbial populations have evolved

sensory systems linked to gene expression to detect metals and respond accordingly.

- Metals as a source or sink for electrons: Metals can be used by microbes in a dissimilatory manner as well. In this case, metals serve as electron acceptors or donors in cell-mediated reactions that contribute to the bioenergetics of the cell.
- Sequestration and resistance: In environments with high concentrations of metals, microbes have developed survival mechanisms that diminish the intracellular toxicity of metals.

26.2.4.1 Direct Association

Since the codification of microbial biofilms as a mode of life (Costerton et al., 1995; Ghannoum and O'Toole, 2001; Stoodley et al., 2002), many communities with populations bound to a substratum have been described as a biofilm. While the existence of biofilm in soils under natural conditions is debated, populations that adhere to soil particles have been identified (Mills and Powelson, 1996) and bacterial isolates of soil have been experimentally determined to form biofilms in the laboratory (Burmølle et al., 2007). Microbes can form biofilms on soil particulates containing metallic compounds (Lower et al., 2001; Luttge et al., 2005) as well as on pure metal (Mansfeld, 2007; Sheng et al., 2008; Waters et al., 2008). Moreover, biofilm matrices and extracellular polysaccharides bind metal ions (Ghannoum and O'Toole, 2001; Teitzel and Parsek, 2003; Raize et al., 2004; Quintelas et al., 2008; Ueshima et al., 2008). It has been noted as well that cells within a biofilm matrix are more resistant to high concentrations of metals (Harrison et al., 2007). Hence, life as biofilm attached to surfaces, including minerals and metals, may provide distinct fitness advantages.

Gorbushina (2007) describes the "subaerial biofilm" that covers the surface of rocks as a relatively simple community composed of fungi, algae, cyanobacteria, and heterotrophic Bacteria and Archaea. Walker and Pace (2007) provides an excellent review that summarizes what we know of community composition of endolithic communities that are typically composed of *Cyanobacteria*, *Actinobacteria*, *Proteobacteria*, and *Bacteriodetes* with other phylogenetic groups found occasionally. It is of course the metabolism of these communities that ultimately alters the rock and contributes to the genesis of soil. Omelon et al. (2007) have correlated endolithic community structure with metal composition of the habitat and concluded that *Cyanobacteria* dominated under higher pH with elevated calcium and magnesium whereas fungi and algae dominated lower pH habitats with elevated iron and aluminum. This suggests that metals were a part of the selective pressures on developing communities. Ultimately, colonization of this type leads to biogeochemical weathering (Barker et al., 1997).

26.2.4.2 Metals as Required Nutrients

Because metals are essential for enzymatic processes and macromolecular structure within microbial cells, elaborate systems for

metal capture and sequestration have evolved. For example, membrane-located influx pumps have been identified for essential metals including iron (Andrews et al., 2003), magnesium (Maguire, 1992), and copper (Lu et al., 1999; Lu and Solioz, 2002). These pumps require contact of the cell with a free or complexed ion in solution. The metal is transported across the outer membrane (Gram-negative cell) by specific energy-requiring receptors. A periplasmic binding protein guides the metal complex to the cytoplasmic membrane transport system and transport to the cytoplasm follows. Many bacteria release a siderophore or hemophore (chelating agent) into the environment to assist in the acquisition of metals (Wandersman and Delepelaire, 2004). Siderophores are low-molecular-weight molecules while hemophores are proteins. Both have relatively high-affinity constants for metals and siderophores can aggressively strip metals from the immediate habitat, a biomediated dissolution of metals. Siderophores complexed with the target metal ion are reassimilated by the cell using specific receptors on the surface. It has been argued that free iron is at low concentrations in every environment. Hence, most bacteria have evolved tactics, for example, siderophores or hemophores, to find and sequester iron. Approximately 500 different siderophores have been described (Wandersman and Delepelaire, 2004), underscoring bacterial diversity and the potential complexity of the soil environment. Because of the importance of iron in cell metabolism, some species have evolved intracellular storage systems that are constructed when iron is abundant. Intracellular storage of iron is mediated by caged structures composed of protein. Three versions have been described, ferritin, bacterioferritin, and Dps proteins (Andrews et al., 2003). These proteins form intracellular multisubunit structures capable of storage of up to 3000 iron atoms.

26.2.4.3 Metals as a Source or Sink for Electrons

Metals are of course essential to the redox chemistry of cells through the coordinated metals within enzymes. What has become recently apparent is the importance of reduction and oxidation of metals in a dissimilatory manner, that is, as donors or acceptors of electrons in reactions that are pivotal to cell bioenergetics (Lovley, 1993; Nealson and Little, 1997; Lloyd, 2003; Lovley et al., 2004). A relatively recent text (Lovley, 2000) provides a good overview of the use of metals as electron donors or acceptors. Perhaps the best-studied organisms capable of dissimilatory metal reduction are *Geobacter* and *Shewanella*. *Geobacter* requires direct contact with insoluble Fe(III) before it can pass metabolic electrons to the metal, reducing it to Fe(II). In contrast, *Shewanella* constructs and excretes soluble quinones or flavin and riboflavins that carry the terminal metabolic electron to Fe(III), perhaps some distance from the cell (Newman and Kolter, 2000; von Canstein et al., 2008). During this process, irregularities on the mineral surface are thought to play a large role in stimulating the process (Brown et al., 1999). These irregularities are the results of imperfect crystallization resulting in series of steps or terraces as one surface gives way to another with each step, providing point defects in the form of kinks in the unit structure. These defects are relevant to the reactivity

of the metal oxide surfaces because they present regions where the energy is perturbed. Rosso et al. (2003) have shown that the dissolution of hematite by *Shewanella*, when using a nonlocal electron transfer system like quinones, can take advantage of structural defects distant from the attached cell. Investigations such as these provide insight into the interactions of microbe and metal at the molecular level.

Finally, microbially synthesized nanowires have been implicated in direct electron transfer, opening a new field of study (Reguera et al., 2005, 2006; Gorby et al., 2006). The specific molecular events leading to the direct transfer of electrons from the cell surface to insoluble metal oxides are not well elucidated but outer membrane cytochromes have been invoked. However, the problem electron transfer has risen to the level of a grand challenge (Fredrickson and Zachara, 2008) and so progress is anticipated. Clearly the microbe must come into direct contact with the mineral surface through an attachment between the outer envelop of the microbe with the mineral surface. The oxidation of metals by microbes is not as well understood. Emerson (2000) provides a good overview of Fe and Mn oxidizers and the geochemical problems they face.

The presence of metals in an environment can dictate a particular life style for microbes. Not only can microbes excrete metal chelating compounds, but also upon sensing the presence of metals (iron in this case) behavioral traits can be stimulated. In the case of *Geobacter* (Childers et al., 2002), insoluble Fe(III) oxide is used as an electron acceptor and soluble Fe(II) is an inducer of flagella and pili synthesis. Hence, it is argued from an ecological perspective that elevated concentrations of Fe(II) are indicative of depleted Fe(III); hence, motility, induced by increasing Fe(II) concentrations, provides the means to relocate to more Fe(III)-rich environs.

26.2.4.4 Resistance and Sequestration

Development of resistance to metals by microbes (Nies, 1992, 1999; Cervantes and Gutierrezcorona, 1994; Silver and Phung, 1996; Barkay et al., 2003) has resulted from long-term exposure to elevated concentrations of metals. Natural environments, for example, serpentine soils (Haferburg and Kothe, 2007), provide habitats for selection under these conditions. Microbes have evolved numerous mechanisms to deal with elevated metal concentrations including efficient and numerous efflux pumps (Nies, 2003). The reference organism for metal resistance is *Cupriavidus metallidurans* (aka *Ralstonia metallidurans*). Originally isolated from metal-contaminated soils, this bacterium has an enormous repertoire of resistance determinants (Mergeay et al., 2003; Noel-Georis et al., 2004). So accomplished is this organism in its interactions with metals that a special issue of *Antonie Van Leeuwenhoek* devoted to *C. metallidurans* is planned (Silver and Mergeay, 2009).

Maintaining nontoxic intracellular concentrations of metals can be accomplished by sequestration as well as pumping. Several examples of microbes capable of binding metals to their extracellular matrix have been described (Sar and D'Souza, 2001; Raize et al., 2004; Lu et al., 2006; Quintelas et al., 2008; Kazy et al., 2009).

In some cases, the binding of metals to dead cells is as effective as it is to live cells (Raize et al., 2004). Not all bacteria have high metal-binding capabilities but clearly those that do can bind significant quantities on their exterior surfaces (Yang et al., 2010). Acting as a large chelator, bacteria can directly influence the transport of metals in the subsurface. Another unusual example of sequestration is the formation of surface blebs or vesicles. Several examples of bacteria capable of producing extracellular vesicles that are enriched in metal have been described (Oremland et al., 2004). This sequestration strategy can accumulate significant quantities of metals, thus altering the distribution of metals locally. In some cases, not only are the metals sequestered but they are also reduced within the vesicle by the bacterium and shifted from the soluble to the insoluble phase.

26.2.5 Discussion

Soils are essential to our survival. However, as our population grows, we are placing soils under increased stress that frequently diminishes their fertility and longevity. The transformation of metals by microbes within the soil environment is a critical process, which, if understood more completely, would assist in the design of sustainable practices. The dynamic equilibrium of metals in soils can be influenced by microbes at every step depicted in Figure 26.3, in both aqueous and solid/colloidal phases. Simply considering the enormous number of siderophores already described makes the combined equilibria of all metals and siderophores, in addition to inorganic binding ligands, a fairly complex equation to solve. Recall that there are approximately 10^9 microbial cells per gram of soil. Haferburg and Kothe (2007) correctly point out that when due consideration is placed on the uncultured majority of the microbes residing in soil, the diversity of known siderophores will increase and the complexity of the equilibria calculations will increase concomitantly. If this is insufficient complexity to challenge the intellect, we might add yet another layer. We have considered the bacteria in our discussions, leaving the viral world unmentioned. Estimates place the concentration of virus at approximately the same order of magnitude as the bacteria in soils (Srinivasiah et al., 2008; Williamson et al., 2010; Section 24.1). Wayne et al. (1975) pointed out three decades ago that bacteriophage Φ80 and an iron siderophore share the same binding site on *Escherichia coli*. Hence, in this one case, producing a siderophore makes one more susceptible to phage. Moreover, the mature virion of T4 has been found to bind metals (Thomassen et al., 2003), adding perhaps many more "chelators" to the mix. One might be led to conclude that the greatest influence on the state of metals in soils is biological.

26.3 Microbially Mediated Processes: Decomposition

E.G. Gregorich

H.H. Janzen

> *In its life, its death, and its decomposition an organism circulates its atoms through the biosphere over and over again.*
>
> **Vladimir Vernadsky**
> *The Biosphere, 1926 (1998, p. 56)*

26.3.1 Overview

Decomposition is the breakdown of complex organic materials, ultimately into inorganic constituents. The process is mediated mostly by microorganisms, which derive energy and nutrients from the process. Consequently, decomposition is influenced by any factor that governs biological processes: primarily water, temperature, and radiation, but also chemical and physical attributes of soil, such as pH, texture, mineralogy, and structure.

Decomposition is critical for continuing life on earth, because it allows the recycling and reuse of carbon (C) and nutrients by biota at local and global scales (Figure 26.5). Although decay is sometimes seen as destructive, it is really a regenerative process,

releasing previously fixed C back to air for renewed photosynthesis, and liberating nitrogen (N), phosphorus, sulfur, and micronutrients to nourish new generations of plants and other biota. If decomposition were to stop, elements essential for life would soon be tied up, extinguishing all organisms (Jenkinson, 1981).

26.3.2 Substrates for Decomposition in Soil

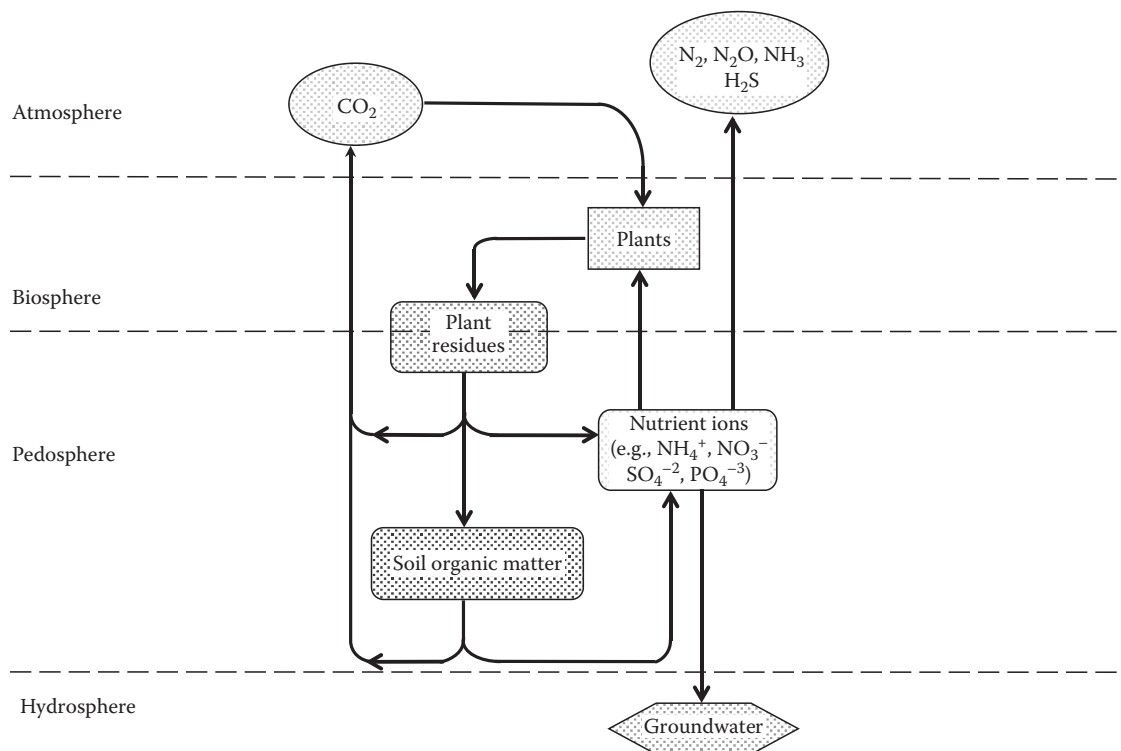
The substrates for decomposition in soil form a continuum, from fresh plant residues to humified organic matter. Fresh plant residues comprise mostly resistant polymers (e.g., cellulose and lignin) with few essential nutrients, but also N-rich cytoplasmic materials such as sugars, amino acids, proteins, nucleic acids, and peptides. Decomposition of fresh plant residues is regulated by three interacting factors: soil organisms, the quality of chemical composition of the residues, and the physical/chemical environment (Figure 26.6). These factors control not just the rate of the process, but also the final products of decomposition. Humified organic matter, at the other end of the spectrum, is a complex product of the condensation reactions of microbial metabolites and refractory plant residues. The decomposition of this material is much slower than that of fresh plant litter, because of the stabilizing effects of its inherent recalcitrance, its association with soil minerals, or its inaccessibility within soil aggregates. Thus, while the rate of plant litter decomposition (primary decomposition) is governed by factors dictating


FIGURE 26.5   The process of decomposition of organic residues is central to biogeochemical cycles encompassing the atmosphere, biosphere, pedosphere, and the hydrosphere.
FIGURE 26.6 Decomposition of fresh organic residues in soil is governed by the interaction of three components: the organisms (O), the quality or chemical composition of the organic substrate (Q), and the physical/chemical environment (P). These components not only determine the rate of the process but also to some extent the final products of decomposition. (Adapted from Swift, M.J., O.W. Heal, and J.M. Anderson. 1979. Decomposition in terrestrial ecosystems. University of California Press, Berkeley, CA.)

microbial activity, that of humus decomposition (secondary decomposition) is controlled more by the intrinsic properties and interactions of the material itself.

26.3.3 Priming Effects of Fresh Residue Inputs to Soil

Soils contain vast amounts of organic matter, most of which is refractory humified material not readily decomposable by microorganisms; substrate availability in soils is therefore both scarce and infrequent. Adding fresh residues often stimulates microbial activity, measurable in accelerated carbon dioxide (CO_2) efflux or N mineralization. Some of this enhanced decay may occur at the expense of humified soil organic matter—the so-called priming effect. Because the turnover of soil organic matter is not measured directly, the priming effects may only be "apparent," reflecting activation of microbial metabolism and higher microbial biomass turnover (Kuzyakov et al., 2000). Mechanisms for "real" priming effects remain unclear but may be linked to accelerated native organic matter turnover from relief of nutrient deficiency (especially that of N) by decay of fresh incoming residues. Alternatively, a burst of energy from decomposable compounds in fresh residues may elicit greater synthesis of enzymes used to hydrolyze more recalcitrant compounds in soil organic matter, that is, cometabolism of soil organic matter (Blagodatskaya and Kuzyakov, 2008).

Research on priming suggests that there may be a complex response of soil microorganisms to the addition of labile organic compounds and decomposition of fresh plant residues. The addition of very small amounts of simple, easily decomposable substances (e.g., glucose and amino acids) and more complex compounds (e.g., soil and compost extracts and root exudates) has been shown to result in more C evolved as CO_2 than was present in the original substrate (De Nobili et al., 2001; Mondini et al., 2006). This finding suggests that trace amounts of easily degradable substances of low molecular weight act as trigger molecules or molecular signals, detected by microorganisms as forerunners to a larger pulse of readily available substrate.

26.3.4 Soil Fauna and Microorganisms

The decay of organic substrates in soil proceeds in incremental fashion, with each successive stage mediated by different biota. Soil fauna are important in early phases; although they account for only a small proportion (usually less than 10%) of soil respiration (Juma and McGill, 1986; Anderson, 1991), they physically fragment organic material, thereby increasing the surface area of the substrate and creating favorable habitats for microorganisms. They also mix and move the organic residues into close contact with the soil, increasing their exposure to microbes and their enzymes and also inoculating substrates with microbes. Soil fauna may further stimulate or inhibit microbial growth and activity through such actions as the deposition of mucus or wastes.

Although soil fauna are important agents of litter comminution and redistribution, the primary agents of mineralization are the microbes (Juma and McGill, 1986). Even in the Antarctic Dry Valleys, one of the harshest environments on earth, decomposition and oxidation to CO_2 of simple and complex substrates are microbially mediated (Hopkins et al., 2006).

26.3.5 Classification of Soil Microorganisms Involved in Decomposition

Different theories have been posited to classify microorganisms involved in the decomposition of organic matter on the basis of their nutritional versatility, affinity for substrates, and/or growth characteristics. Winogradsky (1924) proposed a functional distinction of microorganisms based on their activity and response to substrates in soil. *Authochthonous* organisms, which metabolize recalcitrant organic matter, predominate when there is little oxidizable substrate, growing and reproducing only slowly in soil. *Zymogenous* organisms, which metabolize labile organic matter, respond rapidly to fresh organic matter but become dormant when fresh substrate is depleted. Microbes exist in varying degrees of autochthony and zymogeny, comprising a continuum that ensures the most competitive bacteria will predominate with changes in substrate concentration and condition (Killham and Prosser, 2007).

Another way to classify microorganisms is based on ecological theory relating the density of a species to its soil food supply (Odum, 1953). According to this approach, slow-growing *K*-selected species are adapted to a more continuous supply of energy, where competition is intense. In contrast, fast-growing *r*-selected organisms live under conditions of normally sparse food supply and minimal competition but exhibit rapid growth per unit of food to exploit sporadic flushes of substrate. Yet another classification scheme, adapted from aquatic microbiology (Langer et al., 2004), categorizes organisms as *oligotrophic* (adapted to growth under conditions of C/nutrient starvation) and *copiotrophic* (adapted to C/nutrient stress).

Some researchers question the usefulness of classifying microorganisms based on physiology and function (Killham and Prosser, 2007; Kemmitt et al., 2008), suggesting that such divisions may occur within, as well as among, species; that is,

soil microorganisms are facultatively authochthonous or zymogenous, depending on the prevailing conditions and substrate availability. This view proposes that soil microorganisms are flexible, able to metabolize the wide range of substrates entering soil (Killham and Prosser, 2007).

26.3.6 Spatial Variation of Microbial Communities

Much of the soil microbial community may be dormant because of limited mobility or restricted access to food. But it is a diverse community, capable of surviving extreme environmental and food-related stresses. A notable difference between bacteria and fungi is their mode of growth (Coleman and Crossley, 1997). Bacteria depend on thin layers of water in soil for activity and motility. They are usually clustered in colonies, and their movement is mostly episodic, driven by factors such as rainfall, root growth, tillage, and ingestion by fauna. In contrast, fungal hyphae can grow over relatively large distances and penetrate into small spaces where they can decompose organic matter by secreting enzymes and translocating the nutrients back through the hyphae.

26.3.7 Enzymes

Enzymes catalyze many of the reactions necessary for microbial life, as well as for decomposition of litter. In soil, the activity of enzymes (and hence the rate and extent of decomposition) is regulated by many biotic and abiotic components, including living and latent cells, cell debris, clay minerals, humic colloids, and the soil aqueous phase (Burns, 1982). The location of extracellular enzymes in the soil matrix is determined by the size and solubility of its substrate, the species of microorganism, and the physical/chemical nature of organic and inorganic colloids. The binding of enzymes to soil colloids can extend their activity (some mechanism of association with the humic colloids offers protection but yet permits activity) but adsorption to soil surfaces does not always guarantee subsequent activity (Burns, 1982).

Because of the structural heterogeneity of plant tissues, extracellular enzymes are needed to reduce them to constituent monomers, which microorganisms can then consume. The enzymes most commonly linked to decomposition are hydrolases, which catalyze hydrolysis, and transferases, which catalyze the transfer of chemical groups from one molecule to another (Killham and Prosser, 2007). Other enzymes already widely studied include those prominent in C cycling (e.g., amylase, cellulase, lipase, glucosidases, and invertase), those that catalyze N processes (e.g., proteases, amidases, ureases, and deaminases), and those that promote the release of other nutrients (e.g., phosphatase and arylsulfatase).

A global-scale assessment of enzyme activities in 40 different ecosystems showed that the enzymatic potential for hydrolyzing the labile components of SOM is related to substrate availability, soil pH, and the stoichiometry of microbial nutrient demand (Sinsabaugh et al., 2008). The enzymatic potential for oxidizing the recalcitrant fractions of soil organic material, in contrast, is most strongly related to soil pH.

Most of the current methods for enzyme assays are measurements of potential rather than of in situ activity, and, therefore, results obtained from these methods should be carefully considered (Nannipieri et al., 2002). A full discussion of soil enzyme activities, and the location and properties of enzymes in soil is presented by Landi et al. (2009) and Gianfreda et al. (2009).

26.3.8 Factors Affecting Decomposition

26.3.8.1 Abiotic Mechanisms

Although litter decay is often considered a biological process, abiotic mechanisms can also be important; in some instances—notably arid and semiarid environments—abiotic mechanisms predominate, accounting for as much as two-thirds to three-quarters of the total annual loss from litter (Moorhead and Reynolds, 1989).

Photochemical breakdown of plant litter by solar radiation, particularly the ultraviolet (UV) spectrum, may be a particularly important mechanism of decay in some environments (Pancotto et al., 2005; Gallo et al., 2006, 2009). These losses represent a short circuit in the C cycle, diverting photosynthetically fixed C directly to the atmosphere without cycling through soil organic matter pools (Austin and Vivanco, 2006). Aside from direct photochemical breakdown, solar radiation can also affect decay indirectly, through effects on microbial communities or activity. For example, solar radiation may favor populations that tolerate higher temperatures, lower moisture, and higher levels of UV radiation (Caldwell et al., 2007); affect extracellular enzyme activity or plant litter chemical composition and characteristics; or reduce the stability of extracellular enzymes (Sinsabaugh et al., 2002).

Other abiotic processes of litter decay include leaching, which transfers water-soluble compounds away from decomposing organic matter, and physical abrasion, which breaks substrate into smaller pieces, creating more surfaces for microbial colonization. Because of numerous interactions, mechanisms of decomposition cannot be neatly separated into biotic and abiotic processes; the various processes are interdependent, each influencing the other.

26.3.8.2 Residue Quality

Fresh plant litter consists of mixtures of polysaccharides, polyphenols, celluloses, and lignins of variable composition and abundance and various architectural arrangements (Horwath, 2007). Its C concentration is relatively constant (usually between 40% and 50%) but the concentration of other constituents varies widely; for example, N concentration varies from <0.5% in wood to >10% in protein and bacterial cells.

Various indices have been proposed to describe the effect of residue chemical composition on decomposition. The most common of these, the C:N ratio, rests on the premise that N is the nutrient that most limits decomposition. In residues with wide C:N ratios, decomposition may be slowed because N immobilization exceeds mineralization, resulting in a shortage of available N for the decomposer organisms. The threshold C:N ratio,

above which decomposition is suppressed, is often about 20–30 (corresponding to an N concentration of about 15–25 g kg⁻¹).

The C:N ratio, however, is not an inerrant measure of N availability for decomposition (Jenkinson, 1981). Any factor that increases the rate of decomposition, and hence the N demand, tends to increase the threshold N concentration (narrow the threshold C:N ratio). For example, more favorable moisture or temperature regimes, higher rates of residue application, and a higher proportion of readily available C in the substrate all stimulate greater microbial activity, increase N demand, and increase the threshold N concentration. Laboratory studies, generally performed under favorable conditions, may therefore provide biased estimates of threshold C:N ratios or overstate the impact of residue N content field decomposition rates (Dendooven et al., 1990).

Decomposition depends not only on N content, but also on the lignin, polyphenol, and carbohydrate content of residues (Horwath, 2007). Consequently, various other ratios have been proposed as predictors of the decomposition rate based on observed interactions between N and organic constituents such as lignin, carbohydrates, or polyphenols. Berg (1986) proposed that different factors predominate at progressive stages: early on, the decomposition rate is determined by the concentration of nutrients and readily degradable C, while later, the rate is determined by lignin content.

The composition of the microbial community has an effect on decomposition because the biochemical composition of microbial cells varies among microbial groups (e.g., fungi, G⁺, or G⁻ bacteria). As well, species vary in their output of compounds such as phenols and amino sugars, which, even when produced from labile compounds such as glucose, may be more resistant to decomposition than some plant-derived compounds (Voroney et al., 1989).

Another view of decomposition proposes that it is regulated jointly by the chemical composition of the organic matter and the activity of the microbial community (Moorhead and Sinsabaugh, 2006). A central hypothesis of this view is that the relative amounts of lignin and holocellulose (i.e., cellulose + hemicelluloses) define a threshold for the controls on the process of decomposition. The plant residue chemistry is linked to the activity of the heterotrophic microbial community that comprises three primary guilds: a guild of opportunist microorganisms that consumes labile proteins, grows quickly, and has high affinity for soluble substrates; a guild of decomposer specialists that needs external N inputs, grows more slowly, and has high affinity for holocellulose substrates; and a guild of miners that uses oxidative enzymes to breakdown humus, grows very slowly, and is specialized for degrading lignin.

26.3.8.3 Physical–Chemical Environment

26.3.8.3.1 Water

Water potential affects decomposition, because soil microorganisms depend on water for survival and mobility. As well, water potential can influence decomposition indirectly through effects on O_2 supply, amount of soluble substrate, and pH of the soil solution.

Optimum soil water potentials for decomposition of residue are between −0.01 and −0.05 MPa (Parr and Papendick, 1978). With decreasing water potential, decomposition slows because of reduced microbial activity. Bacterial activity becomes limited first, because of reduced cell mobility and limited availability of substrate (Sommers et al., 1981). Fungi tend to tolerate greater water stress and are capable of surviving at very low water potentials (−4 to −10 MPa). At water potentials higher than about −0.01 MPa, decomposition is slowed by low oxygen tension, because oxygen diffuses more slowly in water than in air.

26.3.8.3.2 Oxygen Supply

The complete decomposition of organic substrates to CO_2 and other inorganic constituents depends on an adequate supply of oxygen. Hence, rates of aerobic decomposition decline when oxygen concentration falls below a threshold level, about 10% according to Schachtschabel et al. (1984; cited by Verburg et al., 1995). Whether oxygen depletion affects decomposition, however, depends on the rate of oxygen replenishment relative to that of oxygen consumption at the site of decomposition. Thus, any factor that reduces rates of oxygen diffusion, such as high moisture content, poor soil structure, or increasing depth within soil, tends to limit oxygen availability. Similarly, oxygen deficiency may be induced by high rates of decomposition (i.e., oxygen consumption) at localized sites. Therefore, even well-drained soils may show appreciable anaerobic activity, presumably in local pockets of low oxygen concentration within soil aggregates (Tiedje et al., 1984).

Although fungi, algae, and many bacteria are usually aerobic, the population in a particular soil may include the full range from obligate aerobes to obligate anaerobes. Some fungi may have the ability to survive anaerobic conditions, though anaerobic activity in soil is dominated by bacteria.

26.3.8.3.3 Temperature

The rate of decomposition is highly responsive to temperature, increasing severalfold over the range found in unfrozen soils (0°C–35°C). Laboratory incubations, for example, suggest that the decomposition rate increases about twofold for a 10° increase (i.e., Q_{10} = 2) between 10°C and 40°C (Stanford et al., 1973), though Q_{10} values may range from 1.6 to 3.2 (Anderson, 1991). Near freezing, microbial activity is constrained more by the absence of liquid water than by low temperature per se. Some activity can occur below 0°C, probably in unfrozen water films around soil colloids.

At a regional level, the effects of temperature on decomposition are reflected in the accumulation of organic matter in soil. Transects of soils in the semiarid, semi-humid, and humid regions in the central United States and Canada show that soils in warm climates contain less organic matter than those in cool regions, in part because of faster decomposition (Jenny, 1941).

Evaluating the effect of temperature on a microbial function like decomposition is difficult, because warming usually results in drier soil conditions, and soil temperature and soil water content have opposite effects on microbial activity. In a study involving

21 cropped sites from different climatic regimes across North America, Insam (1990) observed that the proportion of soil C in the microbial biomass (i.e., C_{mic}-to-C_{org} ratio) was relatively high in arid soils but lowest when the precipitation/evaporation ratio (P/E) was equal to 1. Beyond this point, the proportion increased with increasing P/E. This relationship between P/E and C_{mic}-to-C_{org} ratio suggests that a relatively low microbial biomass is maintained with a given C input and soil water conditions favorable for decomposition. When decomposition is retarded during long drought periods, organic matter is metabolized only during brief periods and a higher C_{mic}-to-C_{org} ratio is maintained because the microbial biomass is active for only a short time. High soil water content may have a similar effect on the C_{mic}-to-C_{org} ratio, because saturated or near-saturated conditions also hinder decomposition, particularly at high temperatures.

26.3.8.3.4 pH

Soil pH affects decomposition by controlling the activity of soil microorganisms. Highly acidic or alkaline soil conditions tend to depress the size of the bacterial community, which prefers near-neutral (pH 6–7.5) soil conditions (Alexander, 1977). Fungi are less sensitive to low pH and usually predominate in acidic soils.

Soil pH also governs the activity of extracellular enzymes immobilized in the soil matrix, each of which has an optimal pH. For example, glycosidases have pH optima between 4 and 6; phenol oxidases, lignin peroxidases, and most proteases have optima between 7 and 9 (Sinsabaugh et al., 2008).

Jenkinson (1977) found that organic material decomposed more slowly in strongly acid soils than in neutral soils. After 1 year, soils with pH 3.7 had more residue than soils with pH 6.9. However, in the long term (>5 years), this difference disappeared, suggesting that the effects of soil acidity on decomposition were predominant in the early stages of decomposition.

26.3.8.3.5 Accessibility

26.3.8.3.5.1 Degree of Physical Protection Organic substrates can be physically protected from microbial and enzyme attack in several ways (Jastrow et al., 2007; Krull et al., 2007). First, clay minerals can adsorb large organic molecules directly, reducing their availability to decomposition. Enzymes that attack the organic molecules may be adsorbed to clay surfaces and become inactivated. Secondly, organic material may be trapped within aggregates (especially microaggregates), which shield them from attack. Most of the habitable space in soil may consist of pores so small that they prevent the entry of most bacteria (Juma, 1993).

Evidence for the physical protection of organic matter within aggregates is the flush of CO_2 that is sometimes released when aggregates are crushed (Elliott, 1986). Chemical analysis of organic material located within aggregates indicates that some of it is relatively undecomposed (Golchin et al., 1994). The capacity of a soil to physically protect organic matter may be limited; Hassink (1996) postulated that this protective capacity is saturated in soils that have not been cultivated or that have been under grass for a long time. According to this hypothesis, the

potential for preserving soil organic matter against microbial activity is directly related to the proportion of the soil's potential protective capacity not yet occupied (Stewart et al., 2008).

The effect of physical protection may be mitigated by other factors. For example, Skene et al. (1997) suggested that physical protection may be the primary deterrent to decomposition of high quality substrates, but that chemical protection (i.e., chemical composition) is the predominant limiting factor in low-quality substrates.

Iron and aluminum oxides, hydroxides, and oxyhydroxides (i.e., FeOx and AlOx) influence the decomposition of soil organic matter because they have extensive and reactive surfaces and therefore a high sorption capacity (Tipping, 1981; Wagi and Mayer, 2007). This high sorptive capacity helps explain observations that metal oxides are often better predictors of soil organic C concentration and have a greater influence on organic C concentration than clay minerals (Eusterhues et al., 2005; Wiseman and Puttmann, 2005). Another important feature of metal oxides related to decomposition is their inhibiting effect on microbial mineralization of organic compounds (Jones and Edwards, 1998).

26.3.8.3.5.2 Particle Size Finely divided organic matter usually decomposes more quickly than coarse organic matter because of increased surface area and greater exposure to microbial activity. In one study, for example, decomposition of straw in an 8–10 month period was 26%–47% faster in mesh bags allowing entry of earthworms than in bags that excluded earthworms (Curry and Byrne, 1992). The effect of particle size, however, varies with time: in early stages, decay may be faster for fine particles than for coarse particles early on, but the trend may be reversed later (Angers and Recous, 1997).

26.3.8.3.5.3 Location Plant litter at the soil surface often decomposes more slowly than that within the matrix of the soil, though the effect of placement diminishes with time (Cogle et al., 1987; Coppens et al., 2006). The initial lag in decomposition of residues on the soil surface is probably attributable to reduced contact with decomposer organisms and to less favorable temperature and moisture conditions, and its magnitude may therefore vary with climate. In cool soils that are poorly drained, decomposition may also be slowed when residues are placed deeper within the profile, for example, by moldboard plowing (Angers et al., 1997).

26.3.8.4 Human Controls on Decomposition

Human modification or management of agricultural, range, and forest ecosystems affects decomposition by altering some of the factors described above. One of the most widespread and pronounced effects on decomposition was the original clearing or cultivation of land for intensive agriculture (Watson, 2000). This land use change often resulted in accelerated decomposition because of changes in water content, aeration, temperature, and accessibility of organic matter. Together with reduced C inputs (because of export in harvests), this enhanced decomposition usually caused depletion in soil C stocks.

Even after the effects of original cultivation have waned, rates of decomposition are influenced by the way lands are managed. Management practices such as tillage, selection of crops and cropping sequences, grazing management, and fertilization can alter decomposition rates through their effects on soil structure, water holding capacity, aeration, temperature, and composition and placement of residues (e.g., Smith et al., 2008a; Johnston et al., 2009). Restoring a semblance of the pre-cultivation tillage, such as by reestablishing permanent grasslands, often induces significant soil C accrual (Conant et al., 2001), presumably, in part because of altered decomposition rates and larger C inputs.

Recently, managing lands to enhance soil C reserves has taken on renewed importance, with growing worries about climate change and the recognition that biological C sinks can, at least in the short term, help slow the accrual of atmospheric CO_2. In general, soil C is lost when grasslands, forest, or other native ecosystems are converted to croplands, or by draining, cultivating, or liming highly organic soils. Conversely, soil C increases when former croplands are restored to grasslands, forests, or native vegetation, or by restoring organic soils to their native condition. In managed lands, practices that increase C inputs to the soil (e.g., increased and/or improved residue and manure management) or reduce losses (e.g., reduced tillage, reduced residue removal) help maintain or even increase soil C levels. Since soil disturbance usually stimulates soil C losses through enhanced decomposition and erosion, reduced- or no-till practices are often suggested as a means of increasing the terrestrial C sink (Smith et al., 2008b). How residue is managed (e.g., whether burned or buried with tillage implements) is also crucial for soil C storage.

26.3.8.5 Methods for Measuring Decomposition

Since decomposition comprises various biological, physical, and chemical processes, a broad range of research techniques and tools has been used to study it (Berg and Laskowski, 2006). Generally, research techniques are divided between field (or in situ) and laboratory methods. Depending on the research objectives, the various techniques can be used equally well, with only minor modifications, in both the field and laboratory, although the interpretation of results may differ between them.

26.3.8.5.1 Field Methods

The most widely used method of measuring residue decomposition in the field is the litter bag technique. In this approach, litter is placed in nondegradable mesh bags and incubated in the field, and mass loss is determined by periodic sampling. This technique has a number of limitations (Heal et al., 1997; Beyaert and Fox, 2008). It measures only net changes and ignores the fate of material leaving the bag; this material may be more labile and contain more nutrients than the residue remaining and so play a key role in other ecosystem processes affecting water and atmospheric quality (Figure 26.5). As well, the exclusion of fauna and vegetation, as well as different climatic conditions in the bag from those of the surrounding soil, may affect decomposition.

Another way to evaluate decomposition in the field is to add labeled (e.g., ^{14}C, ^{13}C, or ^{15}N) plant residues to soil. The residues are usually placed in small cylinders of soil and covered with a mesh screen to prevent contamination by unlabeled material. At periodic intervals, soil is removed from the cylinders and analyzed to measure the quantity of the label remaining. This approach permits direct measurement of the fate of plant litter, and analysis by mass spectrometer or nuclear magnetic resonance (^{13}C NMR) allows for quantitative (i.e., kinetics) and qualitative (i.e., biochemical) changes of decomposition to be accurately measured.

The variation in natural abundance of stable C isotope ratios ($^{13}C/^{12}C$) in plants with different photosynthetic pathways can be used to estimate the proportion of soil organic matter derived from distinct C inputs (Ellert and Rock, 2008). The stable C isotope ratio ($\delta^{13}C$) of soil organic matter is similar to that of the vegetation growing on it. Plants with a C_3 photosynthetic pathway have low $\delta^{13}C$ ratios compared to those with C_4 pathway, and, thus, at sites where the vegetation has changed from one photosynthetic pathway type to the other, the $\delta^{13}C$ ratio of soil organic matter changes in a measurable way. On average, the $\delta^{13}C$ of C_4 plants is 14‰ higher than that of C_3 plants. This large isotopic difference is at least 5–15 times greater than the changes that can be induced by C isotope discrimination during decomposition (Boutton, 1996). This approach is limited to sites with vegetation changes of known date but is powerful because it characterizes C produced in situ and can be used to evaluate soil C dynamics over short (1 year) or long (>100 years) time periods (Balesdent and Mariotti, 1996).

Stable isotope probing (SIP) is a powerful tool that links the taxonomic identity of microorganisms to their metabolic function (Dumont and Murrell, 2005). In soil decomposition studies, SIP involves adding a substrate enriched in a stable isotope (e.g., ^{13}C or ^{15}N) to soil. After a period of incubation during which microorganisms assimilate the stable isotope label, cellular components are extracted from the soil and analyzed for the incorporated label. This incorporation of stable isotopes from labeled compounds into biological signature molecules (i.e., biomarkers) allows for selective detection (e.g., PLFAs by isotope ratio mass spectrometry) or isolation (e.g., DNA and RNA by density centrifugation) of the labeled macromolecules from which the identity of microorganisms can be inferred (Manefield et al., 2002).

26.3.8.5.2 Laboratory Methods

Laboratory incubations permit the detailed study of residue decomposition products and generate information about the decomposition processes. They are usually conducted under favorable temperature and moisture regimes and often exclude processes like faunal activity and nutrient leaching, which influence decomposition in the field. Although the simplified and optimal conditions under which they are conducted prevent direct extrapolation of rates to the field, laboratory incubations are nevertheless useful for characterizing the influence of individual factors on decomposition.

Laboratory incubations with ^{13}C-labeled plant material are valuable in evaluating microbial community level changes during decomposition through analysis of ^{13}C PLFAs (Williams et al., 2006; Moore-Kucera and Dick, 2008). Such isotopic techniques accurately quantify the flow of C into the soil microbial community and identify specific groups of microorganisms responsible for decomposition.

A serious research challenge in evaluating the decomposition of soil organic matter is the development of laboratory methods that extract from soil meaningful fractions of soil organic matter, that is, those that are functionally relevant (Olk and Gregorich, 2006). A useful extraction procedure would isolate meaningful fractions that comprise significant proportions of total soil organic matter and respond in quantity and chemical nature to management or an ecosystem process. Such fractions could be used to elucidate the effects of a management practice or ecosystem process on soil organic matter pools that are cycling at relevant rates.

Comprehensive reviews are available for extractions involving particulate organic matter and the light fraction (Wander, 2004; Gregorich et al., 2006), particle size fractions (Christensen, 1992), aggregate classes (Six et al., 2004), and chemical extractants (Stevenson, 1994).

26.3.8.5.3 *Modeling Methods*

Given the importance of decomposition in understanding fluxes of soil C and N, many soil biogeochemical models have sought to describe the process in a variety of mathematical formulations. There are a number of reviews and comparisons of these models in the literature (McGill, 1996; Paustian et al., 1997; Molina and Smith, 1998; Smith et al., 1998; Wutzler and Reichstein, 2008; Manzoni and Porporato, 2009). The formulations can be an equation or suite of equations that mathematically describe how biotic and abiotic factors regulate the flow of C and N toward more stable forms or mineral pools. When decomposition is viewed as an enzyme-catalyzed reaction a Michaelis–Menten equation is used to characterize the C flow from decomposition in terms of both substrate and enzyme concentration. Some models express the rate of decomposition as constant or linear with respect to the substrate or the microbial biomass, that is, simple first-order kinetics. Multiplicative equations are used to describe the decomposition process when the substrate and microbial biomass are considered to be linked. Some biogeochemical models use complex nonlinear formulations with feedbacks based on microbial function. To date, more than half the models developed are based on first-order decomposition kinetics (Manzoni and Porporato, 2009).

26.3.8.6 Decomposition in a Changing World

Human activity can influence decomposition indirectly by altering global conditions. Increased temperature, by itself, increases the rate of decomposition (Kirschbaum, 1995), and incorporating this observation into simulation models has led to the suggestion that increases in global temperature resulting from an enhanced "greenhouse effect" could accelerate decomposition, resulting in depletion of soil organic matter reserves (Jenkinson

et al., 1991; Kirschbaum, 2000; Jones et al., 2005). Conversely, the greenhouse effect could induce increases in plant-derived C inputs that would exceed the increases in decomposition, resulting in a buildup of soil organic matter levels.

These types of feedbacks to climate change have not yet been clearly elucidated yet (Davidson and Janssens, 2006) because rising temperatures are just one part of a complex suite of changes that would affect the C cycle under global climate change. Precipitation (i.e., water availability) and atmospheric CO_2 concentration (i.e., CO_2 fertilization) would also change. While such changes affect belowground heterotrophic processes, they also influence aboveground photosynthetic processes (i.e., net primary productivity); both sets of processes—dissimilatory and assimilatory—need to be studied to understand the net effect (Heimann and Reichstein, 2008). Decomposition and primary production respond not to average climate but to actual weather conditions, so predictions based on gradual changes in average climate variables and atmospheric gas concentrations may be misleading if climate variability and extremes are ignored.

The effect of temperature becomes even more complicated in the context of the decomposition of soil organic matter that contains myriad organic C compounds, each having different structure, molecular weight, and solubility, and thus different kinetic properties and susceptibility to enzymatic degradation. The more complex soil organic matter compounds are characterized by low decomposition rates, high activation energies, and inherently high temperature sensitivity (Davidson and Janssens, 2006). Since soil organic matter comprises mostly more complex and recalcitrant compounds, the behavior of this pool is crucial to estimating the direction and magnitude of a response to an increase in temperature.

Decomposition of plant residues and soil organic matter has been studied now for many decades, yielding broader understanding of this complex process. But coming global changes will impose new stresses on the global C cycle, and the process of decomposition is at the heart of the C cycle's response to these stresses. Consequently, the study of this critical process in ecosystems worldwide will likely become even more urgent in coming decades.

26.4 Anaerobic Microbially Mediated Processes

Makoto Kimura

Susumu Asakawa

26.4.1 Decomposition Processes of Organic Materials under Anaerobic Conditions

Organisms capable of growing in anaerobic environments can be divided into three groups (Gottschalk and Peinemann, 1992): (1) organisms that are aerobes but can use inorganic oxidized molecules, such as NO_3^-, NO_2^-, MnO_2, and $Fe_2O_3/Fe(OH)_3$ as alternative electron acceptors; (2) organisms that are facultative aerobes but can carry out fermentations in the absence of oxygen and can only carry out the substrate-level phosphorylation under anaerobic conditions; (3) obligately anaerobic bacteria such as sulfate reducers, methanogens, and homoacetogens. In the decomposition of plant residue under waterlogged soil conditions, macromolecules, such as lignocellulose, proteins, and lipids, are generally catabolized to low-molecular-weight organic acids, alcohols, H_2, CO_2, and H_2O by microorganisms belonging to Groups 1 and 2, and these intermediate products are further decomposed to CO_2, CH_4, and H_2O by microorganisms belonging to Group 3.

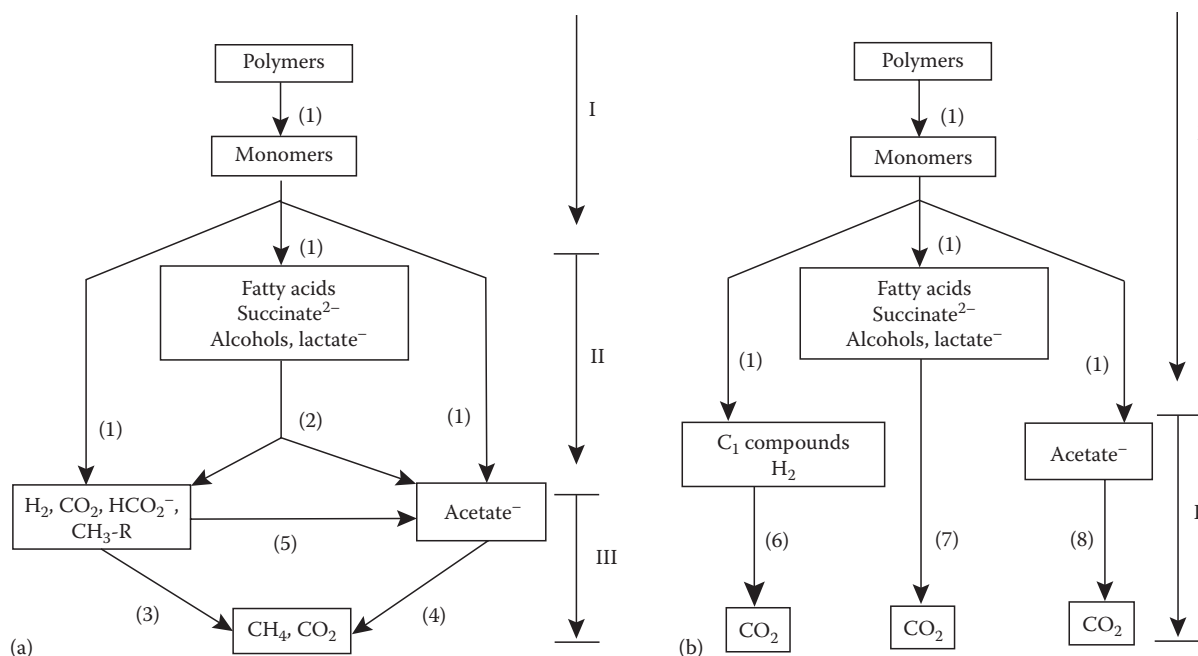
Schink (1997) summarized the decomposition of polymer compounds and relative microbial decomposers in natural ecosystems (Figure 26.7); the complete conversion of polymeric compounds, for example, cellulose, to CH_4 and CO_2 can only occur by the concerted action of at least four different groups of bacteria,


FIGURE 26.7 Scheme for the trophic groups of anaerobes in the (a) Methanogenic and (b) SO_4^{2-}-dependent degradation of complex organic matter. Groups of bacteria involved: (1) primary fermenters; (2) secondary fermenters (obligate syntrophs); (3) hydrogenotrophic methanogens; (4) acetotrophic methanogens; (5) homoacetogens; (6)–(8) SO_4^{2-} reducers. I, II, III: Steps in degradation. (From Kimura, M. 2000. Anaerobic microbiology in waterlogged rice fields, p. 35–138. *In* J.M. Bollag and G. Stotzky (eds.) Soil biochemistry. Vol. 10. Marcel Dekker, New York. With permission from Taylor & Francis Publishers.)

including primary fermenters, secondary fermenters, and two types of methanogens. Polymeric compounds are first degraded by primary fermenters (Group 1) to fermentation products (Step I) as well as to H_2, one-carbon compounds, and acetate. Acetate, H_2, and one-carbon compounds are converted to CH_4 directly by methanogens (Step III, Groups 3 and 4), whereas fatty acids with more than two carbon atoms, alcohols with more than one carbon atom, and branched-chain and aromatic fatty acids are degraded to acetate, H_2, and one-carbon compounds by secondary fermenters (Step II, Group 2). In either metabolic pathways for the degradation of polymeric compounds, H_2-scavenging bacteria (Group 3) have a key role in the overall mineralization, and the syntrophisms between organisms of Groups 2 and 3 are based in many cases on "interspecies H_2 transfer" (transfer of H_2 as an electron carrier between H_2-producing fermentative bacteria and hydrogenotrophic methanogens). Anaerobes of Steps II and III are generally restricted to substrates that they can metabolize, and they depend on fermenters (primary fermenters) (Ehrlich, 1993).

In SO_4^{2-}-rich anoxic habitats, SO_4^{2-} reducers are metabolically versatile and can use all products of primary fermentations and oxidize them to CO_2, simultaneously reducing SO_4^{2-} to S^{2-} (Figure 26.7b). Similar reactions in anoxic habitats can also be conducted by denitrifiers, MnO_2 reducers, and $Fe_2O_3/Fe(OH)_3$ reducers, and polymeric compounds may be metabolized to CO_2 in two steps (i.e., without the involvement of methanogens; Ehrlich, 1993).

26.4.2 H$_2$ Production as an Intermediate Product

Molecular hydrogen (H_2) occupies a unique position in anaerobic metabolism in anoxic soils as an intermediate product of fermentation, and then as a subsequent electron donor for anaerobic respiration. Hydrogen is a common metabolite produced by fermentative microorganisms, and it is used as an electron donor in the enzyme-mediated, energy-yielding reductions by many electron acceptors in soil, such as NO_3^-, MnO_2, $Fe_2O_3/Fe(OH)_3$, SO_4^{2-}, and CO_2. In both aerobic and anaerobic metabolisms of glucose to pyruvate, 2 mol of NADH, 2 mol of ATP, and 2 equivalent $[H^+]$ are produced from 1 mol of glucose (1 glucose $\rightarrow$ 2 pyruvate$^-$ + 2H$^+$ + 2H$_2$). The NADH produced is reoxidized to NAD^+ to continue the reaction, by NADH-linked hydrogenase, which only functions under the low partial pressures of H_2 (NADH + H$^+$ $\rightarrow$ NAD$^+$ + H$_2$). In aerobic microorganisms, O_2 consumes H_2 (2H$_2$ + O$_2$ $\rightarrow$ 2H$_2$O; $\Delta G^{o\prime}$ = −475 kJ mol^{-1} glucose at 25°C and pH 7). Fermentative microorganisms, which cannot use appropriate electron acceptors for scavenging H_2, reduce pyruvate to lactate or ethanol and regenerate NAD$^+$ (2 pyruvate$^-$ + 2H$_2$ $\rightarrow$ 2 lactate$^-$; 2 pyruvate$^-$ + 2H$_2$O + 2H$_2$ $\rightarrow$ 2 ethanol + 2HCO$_3^-$). $\Delta G^{o\prime}$ produced in the pyruvate production reaction is −112 kJ mol^{-1} of glucose at the standard condition (pH 7, 25°C), while the synthesis of 2NADH and 2ATP from 2NAD$^+$ and 2ADP consumes a metabolic energy of 184 kJ mol^{-1} of glucose (Thauer et al., 1977). This apparent

endoergonic reaction becomes exergonic only under conditions of low partial pressure of H_2. In soils, many microbial species can help fermentative microorganisms to regenerate NAD^+ by consuming H_2. The consumption/oxidation of H_2 coupled with appropriate electron acceptors can be associated to growth of fermentative microorganisms. This is called "interspecies H_2 transfer" (Bryant et al., 1967; Reddy et al., 1972). Hydrogen in anaerobic soils can be consumed by denitrifiers, MnO_2 reducers, $Fe_2O_3/Fe(OH)_3$ reducers, SO_4^{2-} reducers, methanogens, and homoacetogens; these reactions keep H_2 at low partial pressure. Consumption of H_2 by "syntrophic" microorganisms permits fermentative microorganisms to further oxidize pyruvate to acetate, producing additional 2 mol of NADH, $2H^+$, and 2 mol of ATP (2 pyruvate$^-$ + $2H_2O \rightarrow$ 2 acetate$^-$ + $2HCO_3^-$ + $2H^+$ + $2H_2$). Thus, the anaerobic decomposition of 1 mol of glucose to acetate produces 4 mol of NADH and 4 mol of ATP (Oremland, 1988).

26.4.3 Denitrification

Denitrification is the process by which NO_3^- and NO_2^- are reduced to nitrogenous gases, mainly to N_2O and N_2, according to the following pathway, $NO_3^- \rightarrow NO_2^- \rightarrow (NO) \rightarrow N_2O \rightarrow N_2$. Microorganisms capable of respiratory denitrification are called denitrifiers. Generally, the major environmental factors that control denitrification are presence of O_2, energy sources and NO_3^- and temperature, pH, and salinity. Waterlogged paddy soils may not experience inhibition of denitrification by acidity because of the pH increase to neutral values due to anaerobic conditions (Ponnamperuma, 1972). The redox potential of waterlogged paddy soils is another environmental factor controlling the reduction rate of NO_3^-.

Almost 130 bacterial species belonging to more than 50 genera can show denitrifying activity. However, half of the identified species are members of only three genera: 28 *Pseudomonas* spp., 13 *Neisseria* spp., and 12 *Bacillus* spp. Generally, only a few denitrifying species are known within a genus. Denitrifiers are predominantly Gram-negative eubacteria, except *Bacillus* spp. (Smith and Tiedje, 1980). Organic compounds are usually oxidized during denitrification, whereas inorganic compounds can only be oxidized by specific groups of microorganisms, for example, sulfur compounds by sulfur-oxidizing bacteria (*Thermothrix*, *Thiobacillus*, *Thiomicrospira*, and *Thiosphaera*), H_2 by hydrogenotrophic bacteria (*Alcaligenes*, *Bradyrhizobium*, *Paracoccus*, *Pseudomonas*, and *Rhizobium*), and NH_4^+ by nitrifying bacteria (*Nitrosomonas* and *Nitrobacter*) (Smith and Tiedje, 1980).

Denitrification coupled with the oxidation of NH_4^+ has been reported by Mulder et al. (1995) in a fluidized bed reactor; 3 mol of nitrate were required to oxidize 5 mol of NH_4^+ ($5NH_4^+$ + $3NO_3^- \rightarrow 4N_2 + 9H_2O + 2H^+$; −297 kJ mol^{-1} NH_4^+). This process, called the "Anammox process," can be carried out by bacteria belonging to the phylum Planctomycetes; three *Candidatus* genera (*Brocadia*, *Scalindua*, and *Kuenenia*) were detected in wastewater treatment plants and aquatic ecosystems (Hayatsu et al., 2008). The anammox process contributes significantly to the N_2 formation in marine environments (Dalsgaard et al., 2003),

freshwater sediments (Penton et al., 2006; Zhang et al., 2007; Dale et al., 2009), and in biofilms (Kindaichi et al., 2007), and, thus, it seems reasonable to hypothesize the presence of the process in anaerobic soils. However, anammox bacteria have not yet been reported in soil environments (Hayatsu et al., 2008).

Nitrous oxide (N_2O), an important greenhouse gas that is predominantly emitted from soil, is an intermediate product in the processes of nitrification and denitrification. Denitrification is the main process that produces N_2O in rice fields under waterlogged conditions. Some soil environmental factors can influence the nitrogenous gases produced (N_2 and N_2O) in the denitrification process. By increasing the concentrations of NO_3^-, NO_2^-, and O_2, it increases the proportion of N_2O produced. By decreasing pH and temperature, it also increases the production of N_2O. On the contrary, a decrease in N_2O proportion is caused by an increase in available carbon, and the mole fraction of N_2O produced decreases in the presence of plants. Conditions that decrease the proportion of N_2O prevail in paddy field soils under waterlogged condition. On the contrary, N_2O production in the nitrification process is predominant under upland soil conditions. It is produced as the by-product in hydroxylamine (NH_2OH) oxidation to NO_2^-, and the production increases by increasing the temperature and application of nitrogenous fertilizers. The N_2O production in the nitrification process is also affected by the kind of crops (Skiba and Smith, 2000).

26.4.4 Dissimilatory Nitrate Reduction to Ammonium

Dissimilatory reduction of nitrate to ammonia (DNRA) $\left(NO_3^- \rightarrow NO_2^- \rightarrow NH_4^+\right)$ is not inhibited by the presence of NH_4^+ or other N compounds. Microbes capable of DNRA include Enterobacteriaceae, or genera such as *Pseudomonas*, *Clostridium*, *Desulfobulbus*, *Desulfovibrio*, and *Bacillus*.

The standard free energy changes of denitrification (NO_3^- + H^+ + $2.5H_2 \rightarrow 0.5N_2 + 3H_2O$) and of DNRA ($NO_3^-$ + $2H^+$ + $4H_2 \rightarrow NH_4^+ + 3H_2O$) are −560.3 and −599.6 kJ per reaction, respectively (Stouthamer, 1988). Thus, the gain of energy from the reduction of each mole of NO_3^- would be similar between denitrification and DNRA, but the gain of ATP by DNRA is less than by denitrification. DNRA is conducted by two groups of microorganisms in soils: One group gets energy directly for cell growth through electron transport phosphorylation of the DNRA processes; one group cannot get energy directly by DNRA and uses this process as an electron sink to reoxidize NADH. In addition, the ATP yield by the first DNRA group is much less than that by denitrifiers due to a difference in the complexity of the respiratory chain (Stouthamer, 1988). DNRA is considered to work as an electron sink in soils.

Tiedje et al. (1982) pointed out the absence of denitrifiers and the predominance of DNRA-microorganisms in the rumen. By considering the relative predominance of DNRA-microorganisms over denitrifiers in several ecosystems with active NO_3^- reduction, they proposed a conceptual model with the dominance of the DNRA process over denitrification in strongly anaerobic habitats, such as the rumen, where the shortage of electron

acceptors is probably the most limiting factor for microbial growth, and DNRA is more favored because it consumes three additional electrons per mole of NO_3^-. On the contrary, in less anaerobic habitats, denitrification is more favored for microbial growth because of the more efficient production of energy per hydrogen supplied in the form of NADH. In general, in water-logged rice fields, denitrification is the dominant process due to the relatively low supply of substrates for the microbial growth by DNRA. Digested sludge, estuarine sediments, and lake sediments present environmental conditions, which are intermediate between those of rumen and those of waterlogged rice fields.

26.4.5 Reduction of MnO_2

Many bacteria, such as *Bacillus*, *Pseudomonas*, *Leptothrix*, and *Micrococcus*, and fungi, such as *Aspergillus*, *Penicillium*, and *Pichia*, can conduct respiration/reduction of MnO_2 (Ghiorse, 1988). Sulfate reducers, such as *Desulfovibrio desulfuricans*, *Desulfomicrobium baculatus*, *Desulfobacterium autotrophicum*, *Desulfuromonas acetoxidans*, and *Geobacter metallireducens*, can oxidize S^0 to SO_4^{2-} when MnO_2 acts as an electron acceptor ($S^0 + 3MnO_2 + 4H^+ \rightarrow SO_4^{2-} + 3Mn^{2+} + 2H_2O$; Lovley and Phillips, 1994). However, several microbial species isolated from paddy soil are also able to reduce MnO_2 in liquid medium by microbial metabolites, indicating that this reaction is widespread among soil microorganisms inhabiting these soils (Kamura and Yoshida, 1972). MnO_2 can also be abiotically reduced by Fe^{2+}. Thus, enzyme-mediated direct reduction (respiratory reduction), indirect reduction by metabolites and chemical reduction are processes reducing MnO_2 in anaerobic soils.

26.4.6 Iron Reduction

Iron reduction in anaerobic soils can involve direct and indirect biological processes. The role of $Fe_2O_3/Fe(OH)_3$ as the terminal electron acceptor was suggested by a significant correlation between the rate of consumption of added glucose and the increase in the amount of Fe^{2+} production in waterlogged paddy soils (Yamanaka and Motomura, 1959). The production of Fe^{2+} was completely inhibited, and a visible change from brownish to grayish soil color due to Fe reduction was not observed when biocides such as NaN_3, $HgCl$, or monoiodacetic acid were added to soil (Yamanaka and Motomura, 1959).

The direct involvement of $Fe_2O_3/Fe(OH)_3$ as a H_2 acceptor in respiration has been shown in bacteria belonging to *Pseudomonas*, *Alteromonas*, *Geobacter*, *Desulfuromonas*, *Pelobacter*, and *Acidiphilium*, which can obtain energy for their growth by the coupling oxidation of H_2 to reduction of $Fe_2O_3/Fe(OH)_3$ (Kimura, 2000). Lovley et al. (1995) suggested that the use of $Fe_2O_3/Fe(OH)_3$ as a terminal electron acceptor can be a characteristic of the *Geobacter–Desulfuromonas–Pelobacter* branch of the δ Proteobacteria. Lovley (1993, 1995) proposed a model for the anaerobic oxidation of organic matter to CO_2 with $Fe_2O_3/Fe(OH)_3$ as the sole electron acceptor; fermentative microorganisms metabolize sugars and amino acids to short-chain fatty acids and H_2. These fermentation products are then oxidized with the reduction of $Fe_2O_3/Fe(OH)_3$.

Microorganisms reducing $Fe_2O_3/Fe(OH)_3$ can use diverse kind of compounds as electron acceptors. For example, $Fe_2O_3/Fe(OH)_3$-reducing *Pseudomonas* sp. strain 200 can reduce NO_3^-, ClO_3^-, MnO_4^-, CrO_7^{2-}, SO_3^{2-}, and $S_2O_3^{2-}$ and thus limit electron flow to $Fe_2O_3/Fe(OH)_3$ (Obuekwe and Westlake, 1982).

Several $Fe_2O_3/Fe(OH)_3$ reducers are present in soils (Ottow, 1969). However, since a few microbial groups can use $Fe_2O_3/Fe(OH)_3$ directly as an electron acceptor, reduction of $Fe_2O_3/Fe(OH)_3$ in soil mainly occurs by indirect microbial reduction. In addition, chemical reduction of $Fe_2O_3/Fe(OH)_3$ by S^{2-} has been shown in soil (Murase and Kimura, 1997). Lovley et al. (1996) found that the $Fe_2O_3/Fe(OH)_3$-reducing microorganisms, *G. metallireducens* and *Shewanella alga*, can use humic substances as an electron acceptor to reduce $Fe_2O_3/Fe(OH)_3$. Reduction of humic substances can also occur by indigenous soil bacteria under anaerobic soil conditions (Lovley et al., 1996). Thus, both direct (enzyme-mediated) and indirect microbial reduction and chemical reduction of $Fe_2O_3/Fe(OH)_3$ can occur in soil under anaerobic conditions.

26.4.7 Sulfate Reduction

Sulfate-reducing bacteria can only be active under strict anaerobic conditions. They include 12 genera of eubacteria, such as *Desulfovibrio*, *Desulfomicrobium*, *Desulfobulbus*, *Desulfobacter*, *Desulfococcus*, *Desulfosarcina*, *Desulfomonile*, *Desulfonema*, *Desulfobotulus*, and *Desulfoarculus* (Gram-negative, nonspore-forming bacteria of the δ subdivision of Proteobacteria), *Desulfotomaculum* (a Gram-positive, sporeforming bacterium), and *Thermodesulfobacterium* (a unique bacterium containing ether lipids). Many of these bacteria can oxidize H_2 and lactate by reducing SO_4^{2-}, and all strains can use not only SO_4^{2-} but also SO_3^{2-}; most of these strains can also reduce $S_2O_3^{2-}$. Acetate is only used by *Desulfobacter* and by some species of *Desulfotomaculum*. Reduction of S^0 is relatively rare for this bacterial group and is restricted to *Desulfovibrio gigas* and a *Desulfomicrobium* sp. (Biebl and Pfennig, 1977; Hansen, 1988). More than 65 compounds are known to be utilized by SO_4^{2-} reducers as energy sources, including H_2, CO, monocarboxylic acids, dicarboxylic acids, alcohols, amino acids, and other miscellaneous compounds (Hansen, 1988).

According to Widdel (1988), SO_4^{2-} reducers are divided into two metabolic groups: (1) species oxidizing their substrates incompletely to acetate ("classical" lactate-oxidizing species, such as *Desulfotomaculum* and *Desulfovibrio*); and (2) species able to oxidize their organic substrates, including acetate, completely to CO_2 (*Desulfobacter*, *Desulfococcus*, *Desulfosarcina*, *Desulfonema*, and *Desulfobacterium*). Therefore, sulfate reducers in the former and latter groups may belong to Groups 1 and 2, and Groups 1, 4, 6, 7, and 8 of Figure 26.7, respectively.

Strains of *Desulfovibrio*, *Desulfomonas*, and *Desulfotomaculum* are the most common SO_4^{2-} reducers in soils. These bacteria only metabolize incompletely a limited number of substrates, such as lactate, ethanol, or dicarboxylic acids to acetate. Therefore,

syntrophy with associated microorganisms is a common way of life for SO_4^{2-} reducers. The syntrophy of SO_4^{2-} reducers with associated microorganisms involves three facets: substrate-yielding, proton-discharging, and proton-scavenging.

Desulfovibrio sulfodismutans disproportionated 1 mol of SO_3^{2-} to 0.75 mol of SO_4^{2-} and 0.25 mol of S^{2-} ($SO_3^{2-} + H^+ \rightarrow 0.75SO_4^{2-} + 0.25HS^-$) and $S_2O_3^{2-}$ to equal amounts of SO_4^{2-} and S^{2-} ($S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+$) (Bak and Cypionka, 1987; Bak and Pfennig, 1987). Bacteria able to disproportionate inorganic S compounds appear to be widely distributed in nature. Bak and Cypionka (1987) counted by the MPN method 2×10^6 cells of $S_2O_3^{2-}$-disproportionating bacteria mL^{-1} of mud in a freshwater ditch sediment. The disproportionation of $S_2O_3^{2-}$ was probably a hydrolytic process by SO_4^{2-} reducers with the inner and the outer S atoms transformed into SO_4^{2-} and S^{2-}, respectively; $S_2O_3^{2-}$ is a key intermediate in the S cycle, being a main product of anoxic S^{2-} oxidation and a shunt between oxidative and reductive pathways (Jørgensen, 1990).

26.4.8 Sulfur Reducers

Both eubacteria and archaeobacteria (Crenarchaeota) can be S (S^0) reducers (Widdel and Pfennig, 1992). Organic substrates, mainly simple organic acids, or H_2 are used as electron donors (Rabus et al., 2006). The archaeobacterial members are extremely thermophilic, may not have a meaningful role in S^0 metabolism in soil (Rabus et al., 2006), and have been isolated exclusively from solfataric soils (Huber and Prangishvili, 2006). Contrary to SO_4^{2-} reducers, some eubacteria and archaeobacteria conducting respiratory S^0 reduction can grow aerobically (Rabus et al., 2006). A *Pseudomonas mendonica*-like strain and *Alteromonas putrefaciens* can use $Fe_2O_3/Fe(OH)_3$, MnO_2, and NO_3^- as electron acceptors, as well as S^0 and $S_2O_3^{2-}$ (Widdel and Hansen, 1992).

A chemolithotrophic pathway, in which S^0 is oxidized to SO_4^{2-} in the presence of either MnO_2 or FeOOH, was discovered in anaerobic marine enrichment cultures, where S^0 was metabolized disproportionately to H_2S and SO_4^{2-} ($4S^0 + 4H_2O \rightarrow SO_4^{2-} + 3H_2S + 2H^+$) (Thamdrup et al., 1993). *Desulfobulbus propionicus* was found to disproportionate S^0 to SO_4^{2-} and S^{2-} (Lovley and Phillips, 1994). When the sediment from a tidal flat was amended with S^0, the production of both SO_4^{2-} and S^{2-} was consistent with the ratio that was expected from the disproportionation reaction ($3S^0 + 2Fe(OH)_3 \rightarrow SO_4^{2-} + 2FeS + 2H_2O + 2H^+$) (Canfield and Thamdrup, 1996).

In the presence of acetate or ethanol, S^0 is shared as an electron-carrying catalyst in the syntrophism between *Desulfuromonas* and green sulfur bacteria (Pfennig and Biebl, 1976), and as little as 0.25 mM of S^{2-} or S^0 was sufficient to maintain their optimal syntrophic growth (Biebl and Pfennig, 1978).

26.4.9 Methanogenesis and Homoacetogenesis

In recent years, CH_4 has received great attention as one of the greenhouse gases. Rice fields are one of the major emission sources of atmospheric CH_4 with an annual emission of 31–112 Tg $year^{-1}$, a considerable output since the total annual CH_4 emission is 582 Tg $year^{-1}$ (Denman et al., 2007). The CH_4 emitted from rice fields probably derives from soil organic matter, rice plants, and applied organic materials (rice straw) (Kimura et al., 2004). In the waterlogged soil pot experiment, the percentages of total CH_4 released from rice soils were 42% from rice straw, 37%–40% from rhizodeposition, and 18%–21% from soil organic matter when the rice straw was applied (6 g kg^{-1} soil in pot) to soil; and 15%–20% from soil organic matter and remaining 80%–85% from rhizodeposition without rice straw application (Watanabe et al., 1999).

Methanogens are a large and diverse group of microorganisms characterized by the production of large quantities of CH_4 as the major product of their energy metabolism; in addition, they are strict anaerobes and are members of the domain Archaea or archaeobacteria (Whitman et al., 1992). Methanogenic archaea comprise five orders: Methanobacteriales, Methanococcales, Methanomicrobiales, Methanosarcinales, and Methanopyrales; members of Methanobacteriales, Methanococcales, Methanomicrobiales, and Methanopyrales can use H_2 and formate (or certain alcohols) as energy sources, while members of the order Methanosarcinales can use a variety of methyl-containing C-1 compounds (Garcia et al., 2000). Acetate is the major source of CH_4 for *Methanosarcina* and *Methanosaeta* (*Methanothrix*) species of Methanosarcinales. The methyl carbon of acetate is reduced to CH_4, and the carboxyl carbon is oxidized to CO_2. The first isolate of the lineage "Rice cluster I," which is commonly detected in paddy field soil by molecular analysis, has been described as *Methanocella paludicola* in a novel order, Methanocellales (Sakai et al., 2008).

Methanogenic activity usually increases sharply after flooding of rice fields, but the methanogenic population survives well under dry and aerobic conditions of rice fields and their numbers do not fluctuate significantly between the fallow season (drained conditions) and the rice cultivation period (waterlogged conditions). There has been a disjunct between the methanogenic populations measured by the MPN method and its activities in rice fields. Fetzer et al. (1993) speculated that the MPN method only detects viable cells of bacterial aggregates, and O_2 might have killed some of the cells localized on external part of aggregate (i.e., the peripheral cells), whereas cells localized in the internal part (i.e., central cells) may have survived.

As each mole of glucose is metabolized to 2 mol of acetate and 4 mol of NADH ($C_6H_{12}O_6 + 2H_2O \rightarrow 2CH_3COO^- + 2HCO_3^- + 4NADH + 4H^+$), two-thirds of the CH_4 in rice fields is theoretically derived from acetate and one-third from CO_2/H_2. In addition, as the partial pressures of H_2 in waterlogged rice fields in situ usually are very low (1–10 Pa) in comparison with K_m values (2.5–12 μM) of hydrogenotrophic methanogenesis (Kimura, 2000) and concentrations of acetate are generally high enough to meet K_m values of acetotrophic methanogenesis (Rothfuss and Conrad, 1993), CH_4 production from acetate seems to be more favorable in rice fields than hydrogenotrophic methanogenesis. However, the number of microorganisms capable of hydrogenotrophic methanogenesis is often higher and their contribution to CH_4 production is often greater than that of microorganisms capable of acetotrophic methanogenesis in rice fields (Schütz et al., 1989; Mayer and Conrad, 1990).

26.4.10 Homoacetogenesis

Homoacetogens are a microbial group that use energy produced by the formation of acetate from H_2 and CO_2 ($2CO_2 + 4H_2 \rightarrow CH_3COOH + 2H_2O$). There are three types of homoacetogenesis: (1) those growing heterotrophically on organic compounds such as sugars, and using the synthesis of acetate from CO_2 as an electron acceptor for metabolic oxidation reactions; (2) those using H_2 and CO_2 as the sole energy sources, and using acetogenesis for the generation of metabolic energy; and (3) those growing on CO as the sole energy source, and producing both H_2 and the carboxyl group from the reaction of CO with H_2O (Diekert, 1992). All of these homoacetogens are strictly anaerobes containing the key enzyme, carbon monoxide dehydrogenase, as well as an enzyme-bound methylcobalamin. Taxonomically, the homoacetogens are an extremely heterogeneous group and include genera of *Acetobacterium*, *Acetogenium*, *Butyribacterium*, *Clostridium*, *Eubacterium*, *Peptostreptococcus*, and *Sporomusa* (Fuchs, 1986; Diekert, 1992).

Chin and Conrad (1995) studied intermediary metabolism in methanogenic rice soil slurry incubated at 15°C and 30°C and found that the lowest temperature decreased the CH_4 production rate with a transient accumulation of acetate, propionate, caproate, lactate, and isopropanol. The added H_2 was consumed, together with CO_2, mainly by methanogenesis at 30°C and mainly by homoacetogenesis at 15°C. The H_2-producing reactions are more sensitive to low temperature than the H_2-consuming reactions, and H_2 consumption by methanogenesis is more sensitive than H_2 consumption by homoacetogenesis (Chin and Conrad, 1995).

Contribution of homoacetogenesis to CO_2/H_2 metabolism is small in a waterlogged Italian rice field (Rothfuss and Conrad, 1993). Similar small contribution of H_2-oxidizing homoacetogens to the consumption of H_2 was observed in sediments of a eutrophic lake, and less than 2% of the total production of acetate in a eutrophic lake sediment was estimated to be derived from homoacetogenesis (Lovley and Klug, 1983). The ratios of methanogens to homoacetogens in lake sediments were ca. 100–1 (Braun et al., 1979).

26.4.11 Competition and Syntrophism among Microbial Groups in Relation to Sequential Reduction

The type of microbial metabolism in waterlogged rice soils changes sequentially according to the oxidation state, from respiration in the presence of O_2 and NO_3^- (most efficient energy-yielding processes) to SO_4^{2-} reduction and methanogenesis (least efficient energy-yielding processes). The Eh_7 of the soil decreases sequentially, according to the respective metabolic processes, from +0.6 to +0.5 V to −0.2 to −0.3 V after submergence (Table 26.2). "Sequentially" does not mean that a subsequent reduction process only starts after the termination of the previous one, but that the time of onset of the respective reduction process occurs sequentially (Kimura, 2000).

TABLE 26.2 Approximate Redox Potentials (mV) at Which the Respective Reactions Start

Reaction	Takai and Kamura (1966)	Takai (1980)	Patrick and Reddy (1978)
Oxygen consumption	+600 to +500	+600 to +300	+380 to +320
Denitrification	+600 to +500	+400 to +100	+280 to +220
Mn^{2+} formation	+600 to +400	+400 to −100	+280 to +220
Fe^{2+} formation	+500 to +300	+200 to −200	+180 to +150
Sulfate reduction	0 to −190	0 to −200	−120 to −180
Methane production	−150 to −190	−200 to −300	−200 to −280
Hydrogen formation	−150 to −220		

Hydrogen is a common electron donor for all microorganisms involved in the sequential reduction processes in anaerobic soils, as explained before. Formate and acetate are the other common electron donors. Competition for H_2, formate, and acetate is, therefore, expected to occur among bacterial groups in anaerobic soils. Differences in K_m and V_{max} of the Michaelis–Menten kinetics of the respective reduction processes seem to explain the sequential reduction commonly observed in waterlogged rice fields. However, the Michaelis–Menten kinetics is only applicable to the competition between SO_4^{2-} reducers and methanogens in the environments with concentrations of H_2 that are 20- to 100-fold greater than those anaerobic soils. Lovley and Goodwin (1988) found that concentrations of H_2 at steady-state conditions depended primarily on the physiological characteristics of microorganism(s) consuming H_2; in addition, they found that microorganisms catalyzing the oxidation of H_2, with the reduction of a more electrochemically positive electron acceptor, can maintain lower concentrations of H_2 than microorganisms using electron acceptors that are reduced at a lower Eh by H_2. In other words, microorganisms responsible for the reduction have their own specific "threshold partial pressures of H_2," and the specific process only occurs above the inherent threshold partial pressure of H_2. The ambient partial pressure of H_2 remains near the specific threshold partial pressure of H_2 as the process continues, and the partial pressure of H_2 increases to higher levels stepwise when more electrochemically positive electron acceptors are consumed. The threshold partial pressure of H_2 is the pressure at which microorganisms metabolizing H_2 can obtain the minimum amount of energy for their growth. It decreases by increasing Gibbs standard free energy $\Delta G^{o\prime}$ obtained from the metabolism of H_2 by electron acceptors. The $\Delta G^{o\prime}$ values of the various processes expressed per mole of glucose at 25°C and pH 7.0 (Thauer et al., 1977) are as follows:

Denitrification ($4H_2 + 1.6H^+ + 16NO_3^- \rightarrow 0.8N_2 + 4.8H_2O$)	$\Delta G^{o\prime} = -896\,kJ$
MnO_2 reduction ($2H_2 + 12H^+ + 4MnO_2 \rightarrow 4Mn^{2+} + 8H_2O$)	$\Delta G^{o\prime} = -556\,kJ$
Fe(III) reduction ($4H_2 + 8Fe^{3+} \rightarrow 8Fe^{2+} + 8H^+$)	$\Delta G^{o\prime} = -275\,kJ$
Sulfate reduction ($4H_2 + SO_4^{2-} + H^+ \rightarrow HS^- + 4H_2O$)	$\Delta G^{o\prime} = -152\,kJ$
Methanogenesis ($4H_2 + HCO_3^- + H^+ \rightarrow CH_4 + 3H_2O$)	$\Delta G^{o\prime} = -136\,kJ$
Homoacetogenesis ($4H_2 + 2HCO_3^- + H^+ \rightarrow CH_3COO^- + 4H_2O$)	$\Delta G^{o\prime} = -105\,kJ$

The threshold partial pressures of H_2 under anaerobic conditions at which microorganisms can carry out the various sequential reduction processes are <0.05 nM for denitrification, <0.05 nM for MnO_2 reduction, 0.03–0.04 Pa for Fe_2O_3/$Fe(OH)_3$ reduction, 0.17–1.9 Pa for sulfate reduction, 0.6–10.6 Pa for methanogenesis, and 51–94 Pa for homoacetogenesis. The threshold partial concentrations of acetate can range from 0.5 to 2.2 μM for sulfate reduction and from 5.2 to 3700 μM for methanogenesis (Kimura, 2000).

26.4.12 Anaerobic Reoxidation of Electron Acceptors

The theory of sequential reduction processes implies that the concentration of reduced products, such as Mn^{2+}, Fe^{2+}, S^{2-}, and CH_4, in soil can increase as the respective reduction processes proceed under anaerobic conditions. However, when several reduction processes take place concurrently in different microsites of soil, the reduced products produced at more reduced sites may be reoxidized at neighboring, less reduced, sites. Several studies have demonstrated the reoxidation of reduced products in anoxic rice soils.

Yoshida and Kamura (1975) observed the oxidation of Fe^{2+} by MnO_2 in a submerged rice soil, and the amount of oxidized Fe^{2+} was equivalent to that of MnO_2 added. When Fe^{2+} was added as $(NH_4)_2Fe(SO_4)_2$ to aerobic paddy soil samples, MnO_2 was reduced to Mn^{2+} chemically with oxidation of Fe^{2+} to Fe_2O_3/$Fe(OH)_3$ (Murase and Kimura, 1997).

Elemental sulfur (S^0) added to rice soil with $NaNO_3$ was oxidized to SO_4^{2-} with reduction of NO_3^- under in waterlogged conditions (Murase and Kimura, 1997). Garcia-Gil and Golterman (1993) observed the FeS-mediated denitrification with SO_4^{2-} formation in river delta sediments, and both NO_3^- reduction and FeS oxidation followed the Michaelis–Menten kinetics (Dannenberg et al., 1992).

Monosulfide (S^{2-}) was reported to reduce $Fe(OH)_3$ chemically with the formation of polysulfide or S^0 in acid sulfate soils (Pons et al., 1982). Addition of S^{2-} ion as Na_2S to aerobic paddy soil samples chemically reduced MnO_2 and Fe_2O_3/$Fe(OH)_3$ to Mn^{2+} and Fe^{2+} (Murase and Kimura, 1997). Lovley and Phillips (1994) also observed S^0 oxidation to SO_4^{2-} coupled with MnO_2 reduction by many SO_4^{2-} reducers.

More than 70% of CH_4 leached from the soil pot disappeared in the subsoil column, indicating anoxic oxidation of CH_4 in a soil pot experiment with and without rice plants over the entire period of rice cultivation (Murase and Kimura, 1994).

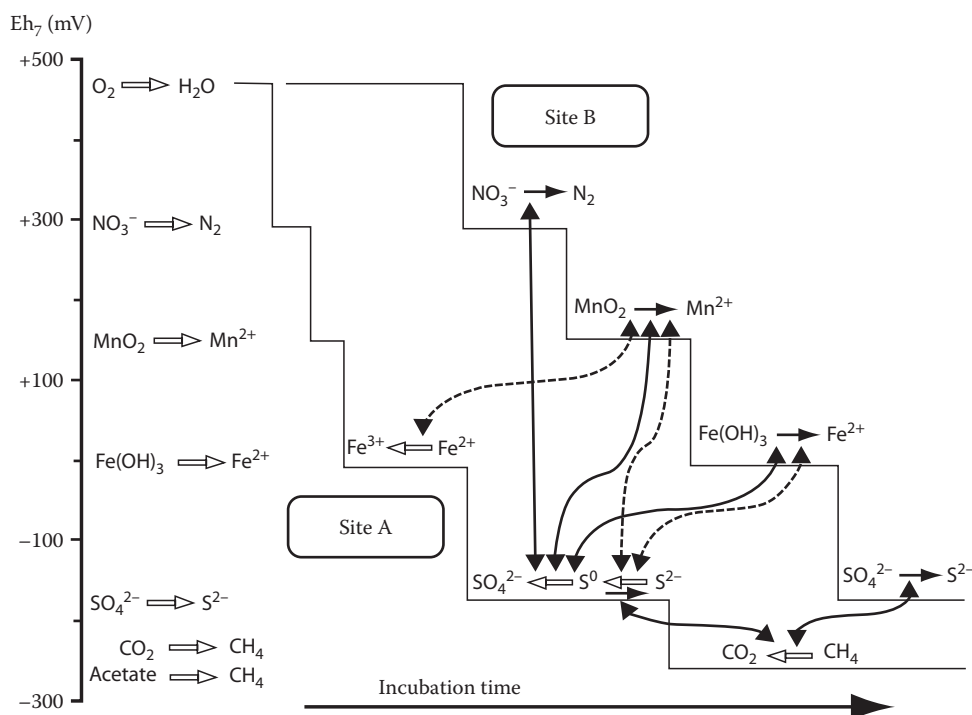
Only few studies on the oxidation of CH_4 in anoxic paddy soils have been reported whereas many studies have shown the anoxic oxidation of CH_4 in fresh and marine waters and sediments, with anaerobic CH_4 oxidizers and SO_4^{2-} reducers working in a syntrophic association. Methane oxidation coupled with SO_4^{2-} reduction is possible thermodynamically ($CH_4 + SO_4^{2-} \rightarrow HCO_3^- + HS^- + H_2O$, $\Delta G^{o\prime} = -16.6$ kJ). The anaerobic CH_4 oxidizers belong to the domain Archaea and are phylogenetically close to methanogens of order Methanosarcinales. They are called "ANME" (anaerobic methane oxidizers) but they have not yet been isolated (Conrad, 2007).


FIGURE 26.8 Conceptual model of reduction processes in submerged rice soils. Solid lines represent biological reactions and dotted lines represent chemical reactions. (From Murase, J., and M. Kimura. 1997. Anaerobic reoxidation of Mn^{2+}, Fe^{2+}, S^0 and S^{2-} in submerged paddy soils. Biol. Fertil. Soils 25:302–306. With permission.)

Results of research mentioned above suggest reconsideration and revision of the prevailing simple reduction sequence model of waterlogged rice soils to a more dynamic model as shown in Figure 26.8, in which two sites with different reduction state are considered (Murase and Kimura, 1997). In the site A, the reduction processes are fast whereas in the site B the processes are slower. Solid and dotted lines indicate microbiological and chemical reoxidation reactions of reduced electron acceptors, respectively, such as CH_4, S^{2-}, S^0, and Fe^{2+}, formed at Site A by SO_4^{2-}, $Fe_2O_3/Fe(OH)_3$ (shown as Fe^{3+} in Figure 26.8), MnO_2, and NO_3^- at Site B. It is reasonable to imagine that these two sites are in communication in soil by water diffusion, water percolation, and water absorption by rice roots. Although it is not yet elucidated how far anaerobic reoxidation occurs in submerged paddy soils, the oxidation–reduction reactions involving "reduced electron acceptors" formed in sites with more reduced states (Site A) and "electron acceptors" of sites with less reduced states (Site B) may balance oxidation–reduction states of waterlogged paddy soil.

26.5 Soil Enzymes

Loretta Landi

Giancarlo Renella

Paolo Nannipieri

26.5.1 Introduction

Considerable information on soil enzymes has accumulated since 1899 when Woods postuled that many transformations of organic compounds in soil might be catalyzed by extracellular enzymes originating from soil organisms. Development in soil enzymology occurred after 1950 (Skujins, 1978a), when research concerned the study of origin, production, stabilization, and persistence of soil enzymes and the role of enzyme activities in the soil–plant system. Several review chapters and some books dealing with soil enzyme have been published (Table 26.3). The knowledge of the origin of enzymes, contributing to the measured soil enzyme activity, can allow a better understanding of organisms actively involved in nutrient dynamics in soil with possible insights into the pathways by which energy and nutrients flow through the soil food web.

It is well established that measured enzyme activity is due to activities from enzymes catalyzing the same reaction not only originating from different sources but having different locations in soil (Burns, 1982; Nannipieri, 1994; Gianfreda and Ruggiero, 2006). Activities of intra- or pericellular enzymes and esoenzymes (those attached to the outer cell membrane), and activities of extracellular enzyme stabilized by surface reactive particles or entrapped by humic molecules are thought to be most important. The former group of enzymes is arbitrarily defined as enzymes associated with living and active microbial cells. Activities of free, extracellular enzymes and enzymes of dead cells and cell debris are considered to be short-lived (being easily degraded) and quantitatively not important (Burns, 1982; Nannipieri et al., 2002). It is methodologically difficult to distinguish between extracellular activity of stabilized enzymes from that of enzymes associated with living organisms. Such separation is important because only the activity of enzymes associated with living microbial cells contributes to microbial activity. This methodological problem makes it difficult to understand the meaning of measurements of enzyme activities in soil, which is their role in plant nutrition and soil fertility, in the metabolism of xenobiotics, and their potential applications in the soil–plant system.

26.5.1.1 Kinetic and Classification of Enzymes

Enzymes, the catalysts of biological systems, are proteins able to increase a million fold or more the speed of a chemical reaction with respect to the same nonenzyme-catalyzed reaction; the enzyme-catalyzed reaction has a lower activation energy and therefore has a faster reaction rate (Tabatabai and Singh, 1976; Dick and Tabatabai, 1978). Active enzymes can require "cofactors." These are small molecules (sometimes inorganic ions),

which are needed to complete the catalytical active structure of the enzyme. For example, Ni is essential for the activity of urease (Dalton et al., 1985). The enzyme without the cofactor is an apoenzyme, and the apoenzyme–cofactor complex is a holoenzyme (Lehninger et al., 1993). Cofactor-requiring enzymes are only active in the intracellular environment because it is almost impossible that the substrate, the cofactor, and the enzyme are present in the same soil microsite to carry out the catalyzed reaction in the extracellular soil environment (Skujins, 1978b).

Like all catalysts, enzymes are not altered at the end of the reaction, and generally, they catalyze specific reactions being substrate specific. For example, proteolytic enzymes hydrolyze peptide bonds in proteins containing L-amino acids but not D-amino acids, and maltase hydrolyzes maltose (α-glucoside) to glucose, whereas cellobiase hydrolyzes cellobiose (β-glucoside) to glucose (Eivazi and Tabatabai, 1988; Lehninger et al., 1993). Enzyme activity depends on pH, ionic strength, temperature,

and the presence or absence of inhibitors or activators (Burns, 1978; Tabatabai, 1982). Enzymes are denatured by elevated temperature and extremes of pH.

The kinetic of enzymes in solution can be described by the Michaelis–Menten equation as follows:

$$V = V_{max}[S]/K_m + [S], \tag{26.2}$$

where
   V is the rate of reaction
   V_{max} is the maximum rate at saturating concentration of the substrate
   S is the substrate
   K_m is the Michaelis–Menten constant (the concentration of S at which $V = V_{max}/2$) and indicates the affinity of the enzyme for the substrate (Lehninger et al., 1993)

It is possible to measure both K_m and V_{max} of most soil enzyme activities measured by reliable protocols (Nannipieri and Gianfreda, 1998). The relative kinetic activity is affected by surface-reactive particles surrounding the enzyme. The effect of the soil colloids, where the enzyme is adsorbed, on the kinetics of the enzyme is discussed by Gianfreda et al. (see Chapter 5 of *Handbook of Soil Sciences: Resource Management and Environmental Impacts*) as well as the resistance of these enzyme complexes to thermal and pH denaturation. Enzymes are classified by the International Enzyme Commission, according to a classification scheme of 1964, and revised in 1972. A name and an enzyme classification (EC) number are given by the committee to identify each enzyme, which is classified according to the catalyzed reaction. The EC number consists of four digits corresponding to four levels of classification. The first digit in the EC number represents the first level of classification, a class indicating the type of catalyzed reaction. These are the main classes of the EC:

- EC 1—oxidoreductases (enzymes that catalyze oxido-reduction reactions)
- EC 2—transferases (enzymes that catalyze the transfer of a chemical group)
- EC 3—hydrolases (enzymes that catalyze the hydrolysis of various bonds)
- EC 4—lyases (enzymes that cleave bonds other than by hydrolysis or oxidation)
- EC 5—isomerases (enzymes that catalyze changes within one molecule)
- EC 6—ligases (enzymes that catalyze the formation of bonds by the cleavage of ATP)

The EC scheme can be found at the JCBN Web site: http://www.chem.qmw.ac.uk/iubmb/enzyme/. Each class includes specific subclasses, which include sub-subclasses. Specific enzyme names generally derive from the substrate of the reaction, followed by the suffix -ase. For example, urease catalyzes the hydrolysis of urea to carbon dioxide and ammonium; maltase hydrolyzes maltose to glucose. In soil biochemistry, enzymes are generally grouped as amidases, decarboxylases, dehydrogenases, lipases, phosphatases, to indicate the type of catalyzed reaction, which usually plays an important role in soil functioning (Burns, 1978; Ladd, 1978). The measured enzyme activity depends on several enzyme catalyzing the same reaction and having different origin and location in the soil matrix.

26.5.2 Origin in Soil

Enzymes in soil may be synthetized by microbial, plant and animal cells but microbial cells are considered to be the most important sources (Ladd, 1985; Torsvik et al., 1996; Nannipieri et al., 2003). Enzyme proteins are the main components of microbial cytoplasm. The distinction between activity of enzymes associated with viable microbial cells and activity of enzymes stabilized in soil is important when enzyme activities are measured as indicators of soil quality or microbial activity since microbial activities are among the most sensitive soil properties to

changes in management practices and environmental conditions (Nannipieri et al., 1996b, 2002).

Soil microorganisms need to release extracellular enzymes to degrade or hydrolyze high-molecular-weight organic compounds into small molecules that can be taken up by microbial cells. Therefore, extracellular enzymes catalyze the initial rate-limiting step of decomposition and nutrient mineralization (Asmar et al., 1994; Sinsabaugh and Moorhead, 1994), and this has been incorporated into mathematical models describing degradation of soil organic matter by Schimel and Weintraub (2003).

It is not possible to include the vast bibliography on the origin of enzymes in soil. We shall only discuss the origin of proteases and phosphatases in soil. Soil proteases, which catalyze the first reaction in protein N mineralization (Ladd and Butler, 1972), are derived mainly from heterotrophic soil bacteria (Nannipieri et al., 1983; Asmar et al., 1992). *Pseudomonas fluorescens*, *Bacillus cereus*, *B. mycoides*, and *Flavobacterium–Cytophaga* spp. can release metalloproteases in a broad range of soil (Hayano et al., 1987; Bach and Munch, 2000). Hayano et al. (1987) reported that metalloproteinases were the dominating proteases in extracts from an andosoil collected from a tomato field, and Janssen (2006) identified *Pseudomonas* as the dominant soil bacteria releasing proteases. Geisseler and Horwath (2008) suggested that microorganisms regulate protease synthesis depending on their needs for C and N sources. Saha et al. (2008) found that high protease activity in manure-treated soil was mainly due to an increased microbial growth, and Kandeler et al. (1999) observed that biomass-specific protease activities of different soils were not related to the organic matter content or texture.

It is hypothesized that in soil, acid phosphomonoesterases are produced mainly by plant roots and fungi whereas alkaline phosphomonoesterases are produced by bacteria (Tabatabai, 1994).

Changes in enzyme activities have been compared with changes in bacterial diversity (Renella et al., 2004). During microbial growth stimulated by adding glucose or plant residue to soil, microbial diversity has been determined by PCR denaturing gradient gel electrophoresis (DGGE) after DNA extraction from soil with the aim to evaluate the microbial origin of phosphatases (Renella et al., 2006b). A better understanding of the origin of soil enzymes has been obtained when specific primers have been developed to amplify "functional genes" involved in enzyme synthesis. In this context, the pivotal contribution is that by Metcalfe et al. (2002), who monitored chitinase activity, bacterial diversity, and genes involved in chitinase production of an untreated (control), sludge- or lime- and sludge-treated pasture soil. The treatments increased chitinase activity and actinobacterium-like chitinase sequences but decreased diversity of chitinases. The approach of combining measurements of enzyme assays and genes involved in the enzymes synthesis (Nannipieri et al., 2008) has been used for assessing the origin of proteases. Sakurai et al. (2007) after PCR amplification of DNA by primers specific for the alkaline metalloprotease (*apr-*) and neutral metalloprotease (*npr-*) genes determined benzyloxycarbonyl phenyllanyl leucine (ZFL) hydrolyzing activity of both rhizosphere and bulk soil fertilized with organic and inorganic

fertilizer and bacterial communities. They found that the composition of proteolytic bacterial communities affected the protease activity of soil. Both soil type and season can influence microbial communities synthetizing metalloproteases (npr) (Mrkonjic Fuka et al., 2009). Casein hydrolyzing activity of an agricultural soil was correlated with the abundance of *sub* genes encoding for subtilisin, the second largest family of serine protease (Mrkonjic Fuka et al., 2008a). The abundance of *sub*-gene containing bacteria decreased with soil depth (Mrkonjic Fuka et al., 2008b).

26.5.3 Enzymes in the Rhizosphere

Plants can positively affect enzymatic activity in soil. Roots can release extracellular enzymes into soil or stimulate microbial activity of rhizosphere soil by rhizodepositions; in the latter case, a new synthesis of microbial enzymes can occur (Ladd, 1985; Tarafdar and Jungk, 1987; Whipps, 1990; Dick, 1994; Nannipieri, 1994; Pinton et al., 2001). As a consequence of the plant effect, enzyme activity is generally higher in the rhizosphere than in the bulk soil. Hydrolase activities of rhizosphere are supposed to play an important role in plant nutrition (Nannipieri et al., 2003). For example, the hydrolysis of organic phosphate monoesters by phosphomonoesterases can account for 30%–80% of P taken up by plants in agricultural soils (Tarafdar and Jungk, 1987; Gilbert et al., 1999). Acid phosphatase was secreted in response to P deficiency by epidermal cells of the main tip roots of white lupin and in the cell walls and intercellular spaces of lateral roots (Gilbert et al., 1999).

Most extracellular enzymes have a low mobility in soil due to their molecular size and charge characteristics, and, thus, any secreted enzyme must operate close to the point of secretion but the substrate may be able to diffuse toward the enzyme (Burns, 1982). The mineralization of the different root exudates and their stimulatory effects on microbial activity is difficult to study because of the broad variety of compounds of rhizodeposition. The study of the effects of a single low-molecular-weight organic molecule requires simple systems mimicking the rhizosphere environment (Badalucco and Kuikman, 2001; Falchini et al., 2003; Landi et al., 2006). These systems create a concentration gradient with higher concentration of the exudate near the root surface. Soil at known distances from the root surface was sampled (Badalucco and Kuikman, 2001). The use of this system has confirmed that root exudates are the main factors controlling microbial activity and community structure in the soil rhizosphere (Landi et al., 2006; Renella et al., 2006a). The rapid increase of microbial growth and hydrolase activities observed in rhizosphere soil by Renella et al. (2006a) suggests that most of the measured enzyme activity is due to intracellular and pericellular enzymes and enzymes attached to the outer surface of viable microbial cells. Different root exudates can have different stimulatory effects on microbial growth and on hydrolase activities (Renella et al., 2006a).

Enzyme activities can also be sensitive to perturbations caused by microbial inoculation (Naseby and Lynch, 1997). Increases in urease, β-glucosidase, and protease activities were related to the increase of the rhizosphere microbial population

as a consequence of bacterial inoculation. Increase in acid phosphatase activity was probably due to a direct fungal secretion or an induced secretion by the plant roots (Joner et al., 2000). The highest concentrations of available P in the rhizosphere of two shrub species inoculated with *Glomus claroideum* were due to the hydrolysis of organic P compounds, probably catalyzed by extracellular, fungal, phosphatase activities.

26.5.4 Production and Persistence

Microorganisms can control synthesis of enzymes at different levels, for example, regulation of gene transcription, posttranscriptional modification of mRNA, and protein cytoplasmic processing after protein synthesis. Allison and Vitousek (2005) suggested a regulation at the level of transcription in soil microorganisms (e.g., enzyme induction and enzyme repression). Both synthesis and persistence of enzyme activities have been quantified in studies based on the stimulation of microbial growth by adding easily degradable organic compounds, such as glucose, or plant material to soil (Ladd and Paul, 1973; Nannipieri et al., 1978, 1979, 1983; Dilly and Nannipieri, 2001; Allison and Vitousek, 2005; Renella et al., 2006b). Enzyme production peaks and persistence depend on the amount and quality of substrate (Balasubramanian et al., 1972; Zantua and Bremner, 1976; McCarty et al., 1992; Allison and Vitousek, 2005). The acid phosphomonoesterase and protease activities were significantly higher in forest than in other soils, probably because of the quality of the soil organic matter (Lahdesmaki and Piispanen, 1988) or to the greater microbial growth (Dilly and Nannipieri, 2001). These studies have shown that enzyme production was not precisely synchronized with microbial growth, as peaks of phosphatase, urease, and protease production proceeded or followed the peak in microbial biomass (Ladd and Paul, 1973; Nannipieri et al., 1978; Renella et al., 2007).

Enzyme production can be an inducible response to the presence of complex substrates (Shackle et al., 2000). However, many enzymes are also produced constitutively by microbes, which may allow them to detect complex resources in the environment (Klonowska et al., 2002). These constitutive enzymes generate low concentration of microbially available products that induce additional enzyme synthesis when complex substrates are abundant. Once concentrations of products increase enough, enzyme synthesis becomes suppressed and production returns to constitutive levels (Chróst, 1991). McCarty et al. (1992) observed that the synthesis of microbial urease was not only dependent on the availability of $N – NH_4^+$ but also on the N metabolites produced by the immobilization of $N – NH_4^+$ taken up by microbial cells.

A simple arithmetical expression has been proposed by Renella et al. (2007) to quantify production (Pr) and persistence (Pe) of enzymes in soil when microbial growth was stimulated by adding glucose and a N source to soil. Greater Pr values of alkaline phosphomonoesterase and phosphodiesterase activities occurred in alkaline than in other soils; it was suggested that the phosphomonoesterase activity with a pH optimum close to soil pH is produced in higher quantities and persists longer than that with a pH optimum further away from that of the soil (Renella

et al., 2007). Significant correlations were observed between the Pr and Pe values of some hydrolases and some soil properties (e.g., alkaline phosphomonoesterase Pr with clay content, acid phosphomonoesterase Pe with soil pH) (Renella et al., 2007), while there was no relationship between phosphomonoesterase production and persistence and bacterial community structure (Renella et al., 2006a).

26.5.5 Role of Soil Constituents in Enzyme Stabilization

It is generally assumed that soil factors such as texture, organic matter content, and pH value are important in stabilizing the released enzymes and that association with clays and/or humic substances can protect the extracellular enzymes from microbial decomposition (Burns, 1982; Nannipieri, 1994). Sorption by soil colloids may protect extracellular enzymes from microbial degradation or chemical hydrolysis, and the adsorbed enzyme can retain its activity for long periods (Nannipieri, 1994). The bibliography on state, activity, and resistance of enzymes adsorbed by surface-reactive particles is extensive and is discussed by Gianfreda et al. (see Chapter 5 of *Handbook of Soil Sciences: Resource Management and Environmental Impacts*). The extraction from soil, partial purification, and characterization of humus–enzyme complexes has shown that the humus network surrounding the entrapped enzyme can allow the passages of substrates and products but not that of proteases (Burns, 1982; Nannipieri et al., 1996b). This model is not valid for enzymes acting on high-molecular-weight substrates (Ladd and Butler, 1972) because the immobilized enzymes should also be susceptible to the attack of protease.

26.5.6 Assays of Soil Enzyme Activity

Enzyme assays in soil are based on the determination of the residual substrate or on the production of the reaction product. Some enzyme assays involve adding, to a soil slurry, either a synthetic substrate linked to a fluorescent molecule (fluorophore) or a substrate forming a colored compound (chromophore) with measurement of the increase in fluorescence and optical absorbance over a fixed incubation time (Saiya-Cork et al., 2002). The high sensitivity of fluorimetric enzyme assays allows detecting enzyme activities of small samples (e.g., rhizosphere samples); an automated assay using a 96-well microplate reader has been developed and can process a high number of different samples (Wirth and Wolf, 1992; Marx et al., 2001; Saiya-Cork et al., 2002; Niemi and Vepsäläinen, 2005).

Tabatabai et al. (1995) have set up several enzymes assays. The protocol is generally based on choosing the optimal conditions (pH, temperature, and substrate concentrations) for the enzyme activity and on using several soils with a broad spectrum of properties. Due to the complexity of the soil system, several analytical problems can interfere on the determination of an enzyme activity such as the fixation of NH_4^+ by clays in enzyme assays based on the determination of NH_4^+ released by enzyme activities such as urease activities (Tabatabai, 1994). The present soil enzyme assays have several limitations: they measure potential rather than actual enzyme activity because soil slurries are generally incubated in the presence of a saturate substrate concentration at optimal temperature values, and with a buffer at optimal pH under shaking conditions. These conditions do not occur in situ (Burns, 1982; Nannipieri et al., 2002; Gianfreda and Ruggiero, 2006). Several methods have been proposed to distinguish these two enzyme activities such as the use of plasmolytic agents or gamma-irradiation (Cawse, 1975; Frankenberger and Johanson, 1986). By assuming that the use of the short-term (up to a few hours) enzyme assays only determine the activity of extracellular stabilized enzymes, Klose and Tabatabai (1999a, 1999b) proposed the soil chloroform fumigation to determine intracellular plus extracellular enzyme activities. No one has proved that the present short-term enzyme assays determine the extracellular stabilized enzyme activity. In addition, proteases are active during fumigation and degrade intracellular enzymes, thus causing an underestimation of intracellular enzyme activities (Nannipieri et al., 2002; Renella et al., 2002). The rapid increase in enzyme activities when microbial growth has been stimulated by adding energy and nutrient sources to soil (see above) has been taken as evidence that most of the measured enzyme activity is due to activities of intracellular and pericellular enzymes and esoenzymes of viable microbial cells (Renella et al., 2006a).

Margon and Fornasier (2008) have investigated location and related kinetics of soil enzymes using a rapid fumigation procedure avoiding proteolysis of intracellular enzymes while ensuring an efficient cell lysis.

A different approach was followed by McLaren and Pukite (1973) and Nannipieri et al. (1996a) to measure the activity of extracellular stabilized enzymes. These authors correlated the number of ureolytic microorganisms to urease activity, and the ATP content to phosphomonoesterase activity, respectively. By extrapolating to zero ureolytic number or the ATP content, the positive intercept on the *y*-axis was assumed to give extracellular urease or phosphatase activity. Microbial numbers, the ATP contents, and both enzyme activities were measured throughout when microbial growth was stimulated by adding glucose and a N source to soil. Advantages and limitations of this approach, called the "Physiological Approach" have been discussed by Nannipieri et al. (2002). One of the limits of this method is that synthesis of enzymes can be repressed during microbial growth as it occurs for phosphatase when inorganic P is added with glucose and the N source to soil (Nannipieri et al., 1978).

26.5.7 Enzyme Activities as Indicators of Soil Fertility and Soil Pollution

Oxidoreductases and hydrolases, the most studied enzyme activities of soil, are involved in the oxidation and release of inorganic nutrients from organic matter (Dick and Tabatabai, 1993). Hydrolases are said to play an important role in plant nutrition (Nannipieri et al., 2002), and for this reason, for example, soil sulfatase activity has been taken as an index of S nutrition in soil (Speir, 1984). There is a growing interest in using soil enzymes as indicators of soil fertility since enzymes are sensitive to numerous

factors such as type of amendment, crop rotations, climate, tillage, and edaphic properties (Skujins, 1978b; Naseby and Lynch, 1997; Ndiaye et al., 2001). For example, positive effects of organic amendments have been observed on the soil hydrolase activities involved in N, P, and C cycling of grassland and degraded soils (Kandeler and Eder, 1993; Garcia and Hernández, 2003).

Organic and inorganic pollutants may reduce soil functionality, by inhibiting hydrolase activities (Tyler et al., 1989). Organic pollutants such as pesticides may affect a sensitive microbial population in soil, but may not change or may increase an enzyme activity as a result of the stimulation of the resistant microorganisms. Repeated addition of a single pesticide, or chemically similar pesticides, generally causes selection of resistant microbial population, and the effect on the enzyme activity can be nil or less pronounced that in the case of single application (Nannipieri, 1994).

Various enzymes can catalyze reactions degrading organic pollutants and reducing contamination of soil. The arylesterase enzyme is involved in the degradation of plastics and hydrolysis of toxic metabolites (e.g., paraoxon) and of organophosphates (Emmelot et al., 1964; Wilde and Kekwick, 1964; Primo-Parmo et al., 1996). Therefore, the measurement of enzyme activity in soil may be important for evaluating the response of soil microbial communities to organic contamination and remediation measures, assessing the fate of pesticides and other organic contaminants potentially toxic to microorganisms and soil organisms (Singh and Jain, 2003; Moon and Smith, 2005). The inhibition of some enzyme activities can occur in metal-polluted soils of both long-term field and laboratory experiments (Tyler, 1974; Tabatabai, 1977; Frankenberger and Tabatabai, 1981; Doelman and Haanstra, 1986, 1989; Tyler et al., 1989; Marzadori et al., 1996; Landi et al., 2000; Moreno et al., 2001; Renella et al., 2003, 2004, 2005; Zornoza et al., 2009).

Unlike organic pollutants, inorganic pollutants cannot be degraded and used as a C source, thus stimulating microbial growth. However, resistant microorganisms can grow by using cell debris of killed, sensitive microorganisms. Thus, changes in enzyme activities of soils polluted with inorganic pollutant are also difficult to be interpreted due to direct and indirect effects of the contaminant. Some investigators have employed the ED_{50} value (i.e., the heavy metal concentration at which enzyme activity is half of the uninhibited level) to describe metal inhibition of soil enzymes (Babich et al., 1983; Haanstra and Doelman, 1991; Moreno et al., 2001; Renella et al., 2003). Using this measurement, Doelman and Haanstra (1989) demonstrated that the influence of heavy metals on acid phosphatase activity in soil depended on differences in texture and organic matter content of soil. The negative impact of trace elements on acid phosphatase was most pronounced in sandy soil. The degree of inhibition also depends on the concentration and form of the metal, the contact time of soil with the contaminant, and the assayed enzyme (Tyler, 1981; Renella et al., 2003, 2004). For example, Moreno et al. (1999) reported that high Cd concentration (>800 mg Cd kg[-1]) inhibited dehydrogenase activity, but not β-glucosidase, urease, and phosphomonoesterase activities. Karaca et al. (2002) observed significant reductions of several hydrolase activities by Cd-enriched (50 mg Cd kg[-1]) sewage

sludge, but urease activity was not inhibited. Renella et al. (2005) reported that long-term exposure of soil microflora to high Cd concentrations (40 mg Cd kg[-1]) reduced hydrolase synthesis and metabolic efficiency. Phytostabilization of trace elements may have beneficial effects on soil functionality due to reduction of trace element mobility in contaminated environmental matrices (Izquierdo et al., 2005; Perez de Mora et al., 2005; Kumpiene et al., 2006, 2007, 2009; Mench et al., 2006; Renella et al., 2008).

Soil contamination can reduce enzyme activity (Dick and Tabatabai, 1992; Nannipieri, 1994; Gianfreda and Bollag, 1996) whereas, an efficient phytostabilization of trace elements can increase enzyme activity and be indicative of the sustainable management of the remediated polluted soils (Kumpiene et al., 2009).

Since soil enzymes differ in origin, function, and location (Burns, 1982) and respond to different key environmental signals, it would be useful to condense the information provided by measuring enzyme activities into a single numerical value. Therefore, complex indices calculated by algebraic combinations of different soil biochemical properties (Nannipieri et al., 2002; Gil-Sotres et al., 2005) or multivariate analysis (Blair et al., 1995) such as principal component analysis (PCA) (Sena et al., 2002) and factorial analysis (Melero et al., 2006; Shukla et al., 2006) have been developed. The validity of these indices or these analyses to different soils and environmental conditions is yet to be proven.

26.5.8 Conclusions

Future research is needed to set up enzyme assays distinguishing enzyme activities associated with living cells and sensitive to environmental change and extracellular enzyme activity stabilized by soil colloids. Enzyme activity of soil should be combined with measurements of genes codifying the enzymes and with measurement of expression of these genes at transcriptional (synthesis of mRNA) and translational (synthesis of specific protein) level so as to evaluate the origin of the measured enzyme activities. Finally, bibliography before the electronic searches should be carefully considered since it is extensive as testified by many review chapters and whole books dedicated to the subject (Table 26.3) so as to avoid "to reinvent the wheel."

27.1 Biological Nitrogen Fixation

Richa Anand

27.1.1 Introduction

Nitrogen is abundant in the atmosphere, lithosphere, and hydrosphere of the earth. However, 99% of nitrogen is in the form of dinitrogen, which is inert and cannot be used by most living organisms. In order for living cells to use it for synthesis of vital bioorganic molecules like proteins, nucleic acids, and vitamins, molecular nitrogen (dinitrogen) has to be in its reduced or fixed form. Dinitrogen fixation, the process by which dinitrogen is reduced to ammonia, is therefore a very important process for the sustenance of life.

Three processes are responsible for most of the dinitrogen fixation in the biosphere. Atmospheric fixation by lightning contributes approximately 5%–8% (5×10^9 kg N year^{-1}) of total fixed

nitrogen (Myrold and Bottomley, 2007). The enormous energy contained in lightning breaks dinitrogen molecules and enables their atoms to combine with oxygen in the air forming nitrogen oxides that dissolve in rain. These oxides of nitrogen then form nitrates that are carried to the earth in rainfall. Industrial nitrogen fixation occurs through a process called the Haber–Bosch industrial process that was established in 1913. This process uses a catalytic agent (iron with a small amount of aluminum added) at high pressure (as much as 5.06×10^7 Pa) and high temperature (600–800 K) and consumes large amounts of fossil fuel. Ammonia produced through this highly expensive process is combined with other elements to produce nitrogenous fertilizers like urea and ammonium nitrate. Although the use of these fertilizers is inevitable in meeting rising food demand to sustain the growing global population, their indiscriminate use has set off very negative effects on water resources and the environment. Approximately 1.1×10^{11} kg N (Myrold and Bottomley, 2007) are manufactured by ammonia industry annually. Increasing fossil

fuel combustion and burning of forests and grasslands contribute approximately 2.5×10^{10} of anthropogenic reactive nitrogen (Nr) (Galloway and Cowling, 2002) that is proving menacing to the environment. Biological nitrogen fixation (BNF), a natural process by which certain prokaryotic microorganisms fix nitrogen by a highly specialized enzyme complex called nitrogenase, is an environmentally benign source of plant-usable fixed nitrogen. According to estimates, approximately 1×10^{11}–1.4×10^{11} kg N (Myrold and Bottomley, 2007) are fixed from the atmosphere by BNF every year. While appreciating the contributions of all sources of fixed nitrogen, this chapter focuses on the process and applications of BNF.

Farmers since ancient Chinese and Roman civilizations have practiced crop rotation with legumes to increase soil fertility and agricultural productivity. However, the science behind such practice was revealed by Boussingault who experimented with leguminous crops fixing N_2 in 1838. In 1886, Hellriegel and Wilfarth showed definitive evidence for N_2 fixation by microbes in legumes.

27.1.2 Nitrogen-Fixing Organisms

The ability to fix nitrogen is limited to bacteria and archaea only. Within these groups, it is quite widely distributed, revealing considerable phylogenetic diversity among diazotrophic organisms. Young (1992) has prepared a comprehensive listing of nitrogen-fixing bacteria and archaea, under 12 broad phylogenetic groups based on 16S rDNA phylogeny including green sulfur bacteria (*Chlorobium*), Firmicutes (*Paenibacillus*, *Clostridium*), thallobacteria (*Frankia*), cyanobacteria (*Anabaena*, *Nostoc*), and all subdivisions of the proteobacteria (α: *Rhizobium*, *Acetobacter*; β: *Azoarcus*, *Herbaspirillum*; γ: *Klebsiella*; δ: *Desulfovibrio*) and archaea (mostly methanotrophs). Dinitrogen-fixing organisms also exhibit quite diverse physiologies (Figure 27.1).

Diazotrophs are also widely distributed ecologically. They are found free living in soils and water (*Klebsiella*, cyanobacteria), in root nodule symbiosis with legumes (*Rhizobium*), associative symbiosis with grasses (*Azoarcus*, *Gluconacetobacter*), actinorhizal associations with woody plants (*Frankia*), cyanobacterial symbiosis with various plants, and symbiotic associations in termite guts.

27.1.3 Chemistry of Nitrogen Fixation

The overall chemical reaction of biological dinitrogen fixation by nitrogenase is represented by the equation

$$N_2 + 8H^+ + 8e^- + 16MgATP \rightarrow 2NH_3 + H_2 + 16MgADP + 16Pi.$$

(27.1)
Due to the stark disparity of energy and heat requirements between chemical and biological N fixation, the structure and function of nitrogenase have always been of immense interest to biochemists (Dance, 2007).

Nitrogenase is a complex enzyme comprising two metalloproteins, the Mo–Fe protein, also called dinitrogenase or component I and the Fe protein called dinitrogenase reductase or component II.

The dinitrogenase responsible for the actual reduction of dinitrogenase to ammonia is a heterotetramer composed of two alpha and two beta subunits with an overall molecular weight of 240 kDa. The Mo–Fe protein contains two types of metal centers, the FeMo-cofactor and the P cluster pair, of which the FeMo-cofactor is the active site where dinitrogen binds, whereas the P cluster mediates electron transfer between the Fe protein and the FeMo-cofactor.

The dinitrogenase reductase or Fe protein is a homodimer of two identical subunits, with an overall molecular mass of ~60 kDa. It contains two ATP/ADP molecules and one 4Fe–4S (Kim and Rees, 1994).

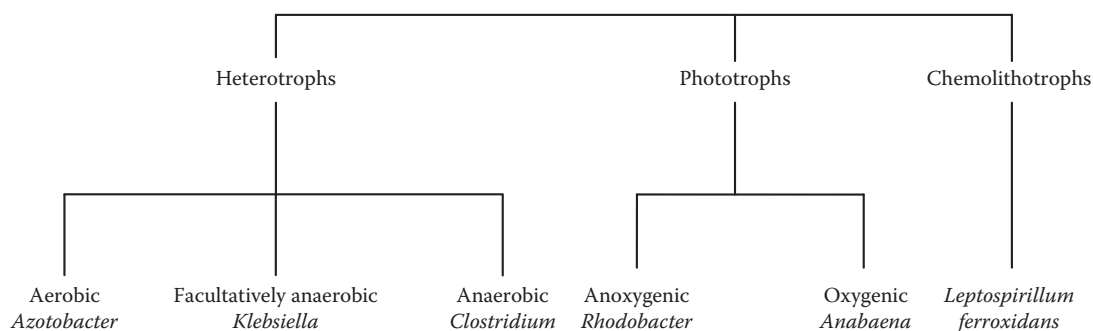
Under conditions of molybdenum depletion, alternative nitrogenase systems may be induced. Molecular genetic studies have shown that Mo-independent nitrogenases are quite widely distributed among diazotrophs and vanadium (V) nitrogenases of *Azotobacter chroococcum* and *A. vinelandii*, and the Fe nitrogenases of *A. vinelandii* and *Rhodobacter capsulatus* are the best known for these (Eady, 1996). *Streptomyces thermoautotrophicus* has been recently found to be able to fix dinitrogen, but it harbors a very unusual N_2-fixing system that requires three proteins for nitrogen fixation, a heterotrimeric molybdenum-containing dinitrogenase (St1), a homodimeric manganese-containing superoxide oxidoreductase (St2), and another heterotrimeric molybdenum-containing carbon monoxide dehydrogenase (St3 or CODH). These proteins differ entirely from the known


FIGURE 27.1 Diversity of diazotrophs based on physiology.

nitrogenase protein components and are insensitive to O_2. Compared to conventional or alternative nitrogenases, the St nitrogenase also requires less ATP (Qi, 2008).

The overall functioning of nitrogenase can be summarized as a key biochemical cycle also called Fe-protein cycle (Dance, 2007), which involves five steps (Kim and Rees, 1994; Dance, 2007): (1) the reduction of Fe protein by electron carriers such as flavodoxin or ferredoxin, (2) association of the reduced Fe protein (including two MgATP complexes) with the Mo–Fe protein in preparation of electron transfer, (3) hydrolysis of MgATP, which enables transfer of one electron to the Mo–Fe protein (via Fe_4S_4 and the P cluster), (4) electron transfer to dinitrogen and thus its reduction, while it is bound to the active site within the Mo–Fe protein, and (5) dissociation of the two protein molecules, exchange of ATP back into the Fe protein, and re-reduction of the Fe protein. Dance (2008) has reviewed chemical catalysis of nitrogenase in detail, addressing questions such as how N_2 binds the FeMo-cofactor, how exactly electrons travel through the system, and finally how NH_3 leaves the complex.

27.1.4 Genetics of Nitrogen Fixation

The structure and function of nitrogenase are coded by close to 20 genes (*nif* genes) organized in 7 operons (*nif* cluster) spanning over 24 kb. These genes fall into three categories: structural, regulatory, and supplementary and can be housed either in genomic DNA or on plasmids (e.g., sym plasmids in *Sinorhizobium meliloti*). The *nif* cluster of the free-living bacterium *Klebsiella pneumoniae* is the most studied of *nif* genes and serves as a model for understanding the regulation, synthesis, and assembly of nitrogenase. The function and arrangement of these genes are described in Figure 27.2.

Genes governing alternative and V-dependent nitrogenases are called *anf* and *vnf* genes, respectively. These genes share extensive homology with *nif* genes with some differences in sequence and arrangement. Eady (1996) has discussed detailed structure, function, and genetics of these alternative nitrogenases.

Other plant and bacterial genes involved in establishing plant–diazotroph interactions such as symbiosis are also known. Of these, the legume genes called *nod* genes are required for the early steps in nodule formation (Debellé et al., 2002). Other genes that are essential for nitrogen fixation by rhizobia but have no homologue in *K. pneumoniae* are known as "*fix*" genes. The most commonly known of these are *fix ABCX*, which are believed to be involved in electron transport, *fix NOPQ*, which are involved in bacteroid respiration under conditions of low oxygen present in nodules, and *fix GHIS* that are involved in redox (Fischer, 1994).

27.1.5 Methods of Studying Biological Nitrogen Fixation

27.1.5.1 Isolation of Diazotrophs from Plants and Soil

Nitrogen-free media with multiple carbon sources are central to the isolation of most culturable diazotrophs. These media used in semisolid state are ideal for simulating the microaerophillic

FIGURE 27.2 Arrangement and functions of various *nif* genes in *K. pneumonia*. Arrows represent the seven operons in which *nif* genes are organized and the direction of translation. (Modified from Madigan, M.T., J.M. Martinko, and J. Parker (eds.). 2000. Metabolic diversity, p. 586–590. *In* Brock's biology of microorganisms. Prentice Hall, Upper Saddle River, NJ.)

conditions ideal for nitrogen fixation. Examples of some such media are yeast extract mannitol (YEM) medium, Vincent's minimal medium (Vincent, 1970), and combined carbon medium (Rennie, 1981). The use of intact pieces (0.5–1.0 cm) of roots and other plant parts has been suggested for isolating diazotrophs adhering to the surface of tissues (Bashan et al., 1993). For isolation of all diazotrophs from a plant, parts are washed and macerated and serially diluted before incubation on semisolid, nitrogen-free medium. Endophytic bacteria are isolated by surface sterilizing tissues before grinding and incubating on medium (Cavalcante and Döbereiner, 1988). Similarly, serial dilutions of rhizospheric and nonrhizospheric soils are used to isolate culturable diazotrophs from soil (Seldin et al., 1983).

Complete communities of culturable as well as unculturable diazotrophs associated with soils and plants can also be profiled using various molecular techniques that utilize the polymorphism in the *nifH* gene, which is believed to be quite conserved across diazotrophs (Zehr et al., 2003), to determine the diversity in the *nifH* gene pool in the target environmental sample. This is done

by amplifying the *nifH* gene by the polymerase chain reaction (PCR) using environmental DNA as a template. The PCR product, which is a pool of almost similar amplicons of various *nifH* genes in the sample, is subjected to subsequent analyses by cloning and sequencing, restriction fragment length polymorphism (RFLP) (Poly et al., 2001), terminal-RFLP (T-RFLP; Deslippe et al., 2005), or by denaturing gradient gel electrophoresis (DGGE; Rosado et al., 1998). These techniques are limited to detecting the presence of diazotrophs in the community but do not provide any information on the frequency of a particular species. Macro- and micro-arrays may reveal both, the presence and frequency of different N_2-fixing prokaryotes (Steward et al., 2004; Moisander et al., 2006).

27.1.5.2 Quantification

The most commonly used methods for measurement of nitrogen fixation are nitrogen balance (also called the nitrogen accretion or nitrogen difference method), the acetylene reduction assay (ARA), xylem solute analysis (ureide production), and stable isotope methods (^{15}N isotope dilution, natural abundance, and incorporation). The major considerations for selection are sensitivity, duration, sample type, and whether relative or absolute rates are required (Myrold and Tiedje, 1986). A more detailed review with examples of application has been done by Danso (1995). The nitrogen balance method is the oldest and simplest method that measures BNF as the difference between the total N contents of plants that fix nitrogen versus those that do not. It is highly dependent and thus disadvantaged by its underlying assumption that both nitrogen fixing and nonfixing control plants absorb equal amount of N from soil. This assumption is hard to justify due to differences in root morphology and other physiological attributes.

The xylem solute method of measuring BNF is based on the determination of the composition of nitrogen compounds in plant tissues or the N flowing through the xylem sap to the shoot. The underlying idea is to differentiate between nitrogen absorbed from soil, which is predominantly nitrate and fixed nitrogen occurring in the form of N solutes, primarily amides and ureides (McClure and Israel, 1979). In the presence of increasing levels of soil nitrate, plants get less dependent on nitrogen fixation and the ureide content of xylem solute decreases. Although the method has sometimes been used to even make quantitative measurements of nitrogen fixation (Herridge, 1984), it is severely hindered by the fact that only a very small proportion of nitrogen-fixing plants export fixed nitrogen in the form of ureides (Van Kessel et al., 1988).

The ARA described by Hardy et al. (1968) is a very popular technique that is used to indirectly measure BNF by estimating enzyme activity based on electron flux through nitrogenase. It is based on the ability of nitrogenase to reduce acetylene ($CH\equiv CH$) to ethylene. Samples to be assayed are incubated in a gas tight chamber that is injected with 0.03–0.1 (v/v) acetylene. The gas collected from the chamber after the end of incubation is assayed for ethylene production using a gas chromatograph fitted with Porapak N or P column. It is a simple, low cost, and sensitive assay that can measure BNF in bacterial cultures, detached nodules, plant parts, or even whole plants. The acceptance of ARA as a sole basis of interpretations of BNF has been hindered by several problems including the short-term nature of the assays, the doubtful validity of always using a conversion ratio of 3 and the autoinhibition of acetylene conversion to ethylene (Danso, 1995).

The stable isotope methods using ^{15}N are more widely used and accepted over all other methods of BNF measurement. These methods are based on the principle that the soil or medium in which plants are grown has a distinctly different $^{15}N/^{14}N$ ratio than the almost constant 0.3663% ratio present in the atmosphere. Therefore, plants incorporating fixed nitrogen from the atmosphere will have a $^{15}N/^{14}N$ ratio different from the substrate they are growing on. When N-fixing plants are grown in air labeled with ^{15}N, they are expected to have an enhanced ratio as compared to substrate (^{15}N incorporation method). Where available soil N is labeled with ^{15}N, a reduction in the ratio is expected when plants incorporate fixed nitrogen from air. This method is also called isotope dilution. Isotope dilution methods rely either on the inherent higher $^{15}N/^{14}N$ ratios of growth substrates than that of the atmosphere (natural abundance) or on ^{15}N enrichment of the substrate via labeled fertilizer. In both cases, a reduced $^{15}N/^{14}N$ ratio indicates nitrogen fixation. However, the enrichment method is more common because of the clearer distinction between substrate and atmospheric ratios, which allows easier detection using relatively less costly equipment (Danso et al., 1993).

27.1.6 Nitrogen Fixation in Agriculture and Forestry

Biological N_2 fixation contributes to productivity both directly, where the fixed N_2 is harvested in grain or other food for human or animal consumption, or indirectly, by contributing to the maintenance or enhancement of soil fertility in the agricultural system by adding N to the soil (Giller and Cadisch, 1995). Among symbiotic N_2-fixing systems, nodulated legumes have been used in cropping systems for centuries. They can serve a multitude of purposes in sustainable agriculture. They are used as primary sources of food, fuel, fiber, and fertilizer, or, secondarily, to enrich the soil, preserve moisture, and prevent soil erosion. The *Rhizobium*–legume symbiosis was the focus of agronomic practices and nitrogen fixation research during the nineteenth century and for most part of the twentieth century. However, since the latter half of the twentieth century, researchers have started focusing on extending nitrogen fixation to include nonlegumes as well. Efforts have been made to induce paranodules on roots and inoculate them with effective rhizobial strains (Cocking et al., 1995). The process involves application of auxins, cell wall–degrading enzymes, or genetic modification of bacteria that are not very practical for field application (Bruijn et al., 1995). Exploration of naturally occurring diazotrophic associations in nonlegumes has proven to be a better approach (James and Olivares, 1998). Sugarcane research in Brazil presents a valuable example of this approach. The observation that sugarcane had always been grown successfully in Brazil with little or no nitrogen inputs led Döbereiner (1961) to suggest that sugarcane might be meeting its nitrogen demands with the help of naturally associated nitrogen-fixing bacteria.

Early efforts to explore diazotrophs in sugarcane fields resulted in the isolation of bacteria of the genus *Beijerinckia* in high numbers, with selective enrichment in the rhizosphere and especially on the root surface (Döbereiner, 1961). Diazotrophes of the genera *Erwinia*, *Azotobacter*, *Derxia*, *Azospirillum*, and *Enterobacter* (Purchase, 1980; Gracioli and Ruschel, 1981) were also found from the roots, stems, and even leaves of sugarcane. However, none of these bacteria seemed to occur in large enough numbers to account for the 38–77 Kg N ha^{-1} of mean annual BNF input reported in various studies (Oliveira et al., 1994; Boddey et al., 1995). In 1988, Cavalcante and Döbereiner found an extraordinary diazotroph, *Gluconacetobacter diazotrophicus*, in large numbers within the roots and stems of sugarcane. It is a small, Gram negative, aerobic rod-like bacterium that can grow on very high concentrations of sugar and has the capability to fix N (>100n mol C$_2$H$_2$ mL^{-1} ha^{-1}) at a pH as low as 3 (Stephan et al., 1991) and oxygen levels of 4 kPa (Reis et al., 1990). Its ability to fix nitrogen is also not affected by the presence of high levels of nitrate (Boddey et al., 1991). The discovery of a bacterium possessing such unique properties adapted to fixing nitrogen under conditions very specific to the interiors of a sugarcane plant has encouraged researchers to believe that such systems might be in place for other nonlegumes waiting to be discovered. Some other examples of diazotrophic bacteria associated with other nonlegumes are *Herbaspirillum*, *Azospirillum*, and *Klebsiella* with corn (Chelius and Triplett, 2001), *Herbaspirillum*–rice (Baldani et al., 1986), *Azospirillum*–wetland rice (Döbereiner and Pedrosa, 1987), *Azoarcus*–kallar grass (Reinhold-Hurek et al., 1993). Such associations are also found in horticultural plants, for example, *Burkholderia* with tomato (Caballero-Mellado et al., 2007), *K. variicola* with banana (Martínez et al., 2003), *Azotobacter* with pepper (Govedarica et al., 1997).

Studies revealing associations between endophytic diazotrophic bacteria and forest trees, particularly lodgepole pine are underway in our laboratory and have been described in Anand et al. (2006). These studies are expected to help answer long-standing questions about the presence of unexplained nitrogen in some forest ecosystems (Fenn et al., 1998; Binkley et al., 2000).

Despite much advancement in our basic knowledge of associative nitrogen fixation, the extent of true benefits from it in the field remains to be established especially in temperate agriculture (Peoples, 2006).

27.1.7 Biological Nitrogen Fixation: Economy and Environment

The economic and environmental costs of the heavy use of chemical N fertilizers in agriculture are a cause of global concern. The manufacture of nitrogenous fertilizers is heavily dependent on the already dwindling and disputed reserves of fossil fuel. Their excessive application has adverse effects on human health (methemoglobinemia in infants, cancer, respiratory illness) and the environment (nitrate leaching into water sources, eutrophication, plant toxicity, ozone depletion; Bohlool et al., 1992). BNF is an economically feasible and environmentally benign process that can be used alone or in conjunction with nitrogenous fertilizers to sustain food production particularly in the poor and developing countries where more than 78% of the world's population resides (Khush, 2001). The Food and Agricultural Organization emphasizes on the importance of beans and other legumes in the diets of people in these parts of the world. The contribution of BNF to the social and economic success of Brazil through bean and sugarcane cultivation (Döbereiner, 1997) is an important model for the potential of this nitrogen input in the developing countries in the tropics and subtropics.

Another important economic and environmental application of BNF is in the cultivation of energy crops like sugarcane, for the production of biofuels (Döbereiner, 1997). The elimination of N fertilizer for the production of biofuel crops, such as sugarcane, represents the key to high-energy balances because N fertilizer is produced by reduction of atmospheric N$_2$ to NH$_4$, using natural gas as an energy source (Reis et al., 2007). Brazil where subsidies on nitrogen fertilizers are traditionally low and sugarcane is grown with the help of natural and inoculant-aided BNF (Boddey et al., 1995) has been really successful in producing and utilizing these biofuels. Baldani et al. (2002) have reported that as many as three million cars in Brazil run on 95% hydrous ethanol and all gasoline sold in Brazil contains 20%–24% ethanol as biofuel.

Nitrogen-fixing bacteria have also been found to be useful for bioremediation of industrial waste and hydrocarbon spills. Ikechukwu and Onwurah (1999) found that *Azotobacter* played a role in bioremediation of soil polluted with crude oil by providing other bacteria with nitrogen and through some cometabolic activities. Some diazotrophs isolated from petrochemical sludge have the ability to degrade organic contaminants like polyethylene glycol, naphthalene, and hexadecane (Naumova et al., 2009).

27.1.8 Factors Limiting Biological Nitrogen Fixation

Bohlool et al. (1992) have categorized the constraints to practical application of BNF systems as environmental, biological, methodological, and sociocultural.

Major environmental constraints are concerned with conditions affecting the microbe, the host, or their symbiotic interaction. These include soil acidity, aluminum and manganese toxicity, sulfur and phosphorus deficiency (law of minimum), salinity, and soil aeration. A thorough understanding of these factors and how they affect different BNF systems is required to overcome these limitations. A major obstacle to successful establishment and effective performance of introduced N$_2$-fixing systems is also competition from native organisms.

A variety of biological constraints may influence the expression of BNF in all nitrogen-fixing systems. Both plants and bacteria are subject to biological constraints, such as disease and predation that can directly or indirectly affect the amount of N fixed. In general, the amount of nitrogen fixed is directly related to the growth potential of the host in a particular system. When growth is limited, for example, by disease, nitrogen fixation will be reduced accordingly.

Identification, preparation, and application of diazotrophic inoculants are major methodological constraints to widespread field application of BNF systems. The scale of production, the availability of suitable carrier material, and shelf life of the finished product limit the use of inoculants, especially in developing countries. Various cultural, educational, economic, and political factors also affect fuller implementation of BNF. Small and subsistence farmers lack the awareness and means to utilize this technology, especially in developing countries, while subsidies on nitrogen fertilizers (Bohlool et al., 1992) in both developed and developing countries, are a huge disincentive to the use of BNF, for medium and large farms. Giller and Cadisch (1995) have discussed these constraints and ideas for overcoming them, with examples from Asia, Africa, Europe, and North America.

27.2 Nitrogen Mineralization–Immobilization Turnover

Jeanette M. Norton

Joshua P. Schimel

27.2.1 Introduction

The N cycle is complex and seemingly becoming more so with new processes being discovered regularly, but the core of the cycle remains the transformations between organic and inorganic nitrogen (N) (Schimel and Bennett, 2004). These transformations regulate critical ecosystem processes including plant growth, trace gas emissions, and NO_3^- leaching into ground and surface waters. They impact either directly or indirectly almost all the processes involved in the N cycle. Research focused on a wide variety of topics is needed to adequately assess the dynamics of the transformation of N between organic and inorganic forms. However, the best approach to understanding these processes is not always obvious and will vary depending on the specific study objectives.

Mineralization is the general term for the conversion of organic N to inorganic N as either ammonium (NH_4^+) or nitrite/nitrate (NO_2^-/NO_3^-), ammonification is the conversion of organic N to the NH_4^+ form, while nitrification (see Section 27.3) is the oxidation of reduced N (NH_4^+ or organic N) to NO_2^-/NO_3^-. Immobilization is the assimilation of inorganic N to organic N generally mediated by microorganisms. Mineralization–immobilization turnover (MIT) refers to the combined transformations between organic and inorganic N that accompanies the growth and death of the soil biota. To what extent MIT in soils necessitates passage through the NH_4^+ pool remains a subject of debate (Schimel and Bennett, 2004), as both plants and microorganisms can take up and use small N-containing compounds (i.e., amino acids, amines, etc.) without having to release the N as NH_4^+. An overview of these soil N cycle transformations is given in Figure 27.3.

27.2.2 Biochemistry and Physiology of Mineralization

As microorganisms decompose organic matter, including the remains of plants, animals, and microorganisms, they use as much

of the N as they need, while they release the remainder as smaller molecules or NH_4^+. This means that N mineralization is not a single physiological process, but rather, the aggregation of multiple physiological processes that result in the production of N waste materials (Ladd and Jackson, 1982).

Mineralization of organic N is basically a sequence of enzymatic reactions. The first step in this process is often to break down the large polymers that contain the bulk of N in the biota. This depolymerization is carried out by extracellular enzymes (primarily microbial in origin) including the proteinases, chitinases, kinases, amidases, and amidohydrolases (Ladd and Jackson, 1982). The substrates for depolymerization include a broad range of proteins, microbial cell wall constituents (amino sugars and their polymers, chitin, and peptidoglycan), and nucleic acids. Nitrogen is also released from the various N compounds found in soil organic matter including a considerable amount of heterocyclic and phenolic N, which are processed slowly in most soils.

Exoenzymes decrease the size and complexity of organic N molecules facilitating their further decomposition or assimilation; this depolymerization is often the rate-limiting step in the mineralization process (Kemmitt et al., 2008; Wallenstein and Weintraub, 2008; Jones et al., 2009). Some of the specific enzymes, which are involved in mineralization and their reactions, are summarized in Table 27.1. Since proteins and peptides are major sources of mineralizable N, the enzymes that can degrade these are produced abundantly and in wide diversity by microorganisms. Two examples of proteinases are trypsin, a specific enzyme that cleaves peptides at lysine and arginine residues, and subtilisin, an enzyme with broad specificity for peptide bonds that hydrolyzes a number of peptide amides. Fungi produce many proteolytic enzymes that may be particularly important for N acquisition during growth on woody substrates (Kudryavtseva et al., 2008).

The release of N from nonpeptide C–N bonds in amino acids and urea is mediated by amidohydrolases, dehydrogenases such as glutamate dehydrogenase (GDH) and transaminases. Peptidoglycan hydrolase acts on the link between *N*-acetylmuramoyl residues and L-amino acid residues in cell wall glycopeptides, thus playing a central role in the decomposition and turnover of microbial biomass. The polymers of amino sugars that are important components of bacterial and fungal cell walls are hydrolyzed by glycosidases. Other amidohydrolases, which are considered to be important for N mineralization in soils, include L-asparaginase, L-glutaminase, and amidases. Chitinase acts upon chitin and chitodextrins, major
FIGURE 27.3 Overview of soil N cycle with emphasis on nitrogen mineralization–immobilization turnover. (From Schimel, J.P., and J. Bennett. 2004. Nitrogen mineralization: Challenges of a changing paradigm. Ecology 85:591–602.)

TABLE 27.1 Representative Enzymes Involved in N Mineralization in Soil Microorganisms

Enzyme	EC Designation	Action
Proteinases/peptidases	3.4	Hydrolyze peptide bonds
Trypsin	3.4.21.4	Hydrolyzes at Arg, Lys
Chymotrypsin	3.4.21.1	Hydrolyzes at aromatic amino acids
Subtilisin (microbial alkaline proteinase)	3.4.21.14	Alkaline proteinase
Carboxyl proteinases	3.4.23	Acid proteinases similar to pepsin or rennin
Microbial metalloproteinases	3.4.24	Neutral proteinases containing Zn
Amidohydrolases	3.5.1	Hydrolysis C–N bond in linear amides
L-Asparaginase	3.5.1.1	Hydrolysis of L-asparagine
L-Glutaminase	3.5.1.2	Hydrolysis of L-glutamine
Amidase	3.5.1.4	Hydrolysis of aliphatic amides
Urease	3.5.1.5	Hydrolysis of urea to CO_2 and NH_3
Peptidoglycan hydrolase	3.5.1.28	Hydrolysis of peptidoglycan linkages
Amidinohydrolases	3.5.3	Hydrolysis C–N bond of linear amidines
Arginase	3.5.3.1	Hydrolysis of arginine to ornithine and urea
Transaminases	2.6.1	Transfers amine to α-ketoglutarate
Dehydrogenases that deaminate	1.4	
Glutamate dehydrogenase	1.4.1.3	Deaminates glutamate
Glycosidases	3.2	Important in hydrolysis of amino sugars and their polymers
Chitinase	3.2.1.14	Hydrolyze chitin linkages
Muramidase (lysozyme)	3.2.1.17	Hydrolyze muropeptide (peptidoglycan) or mucopolysaccharide
Nucleases	3.1.11-16	Degrade DNA and RNA
DNase	3.1.11	Exodeoxyribonuclease
RNase	3.1.13	Exoribonuclease

Source: Chang, A., M. Scheer, A. Grote, I. Schomburg, and D. Schomburg. 2009. BRENDA, AMENDA and FRENDA the enzyme information system: New content and tools in 2009. Nucleic Acids Res. 37:D588–D592.

compounds in fungi, exoskeleton of insects, and crustaceans (Alef and Nannipieri, 1995). The observation that free nucleic acids are degraded rapidly substantiates the ubiquitous presence of the nucleases in the soil environment (Pietramellara et al., 2009).

There are two approaches to measuring the activity of specific extracellular enzymes. One is to inhibit microbial activity and then to measure the production of the enzymatic products—this is sometimes considered an "actual" enzyme rate, although there are serious constraints on the approach. The other is to add specific substrates and to measure the reaction rate—this is usually described as an enzyme potential. As with most soil assays, they each have their own strengths and limitations and neither is perfect for all applications (Burns, 1982; Nannipieri et al., 2002; Wallenstein and Weintraub, 2008).

To measure "actual" protease activity, microbial amino acid uptake is inhibited, usually by toluene, and then the rate of amino acids accumulation is measured (Tabatabai, 1994). That rate is considered the protease activity. The strength of this approach is that it does not require an added substrate, and so there is some hope that the measured rate actually does reflect the rate of proteolysis that occurs in the soil. However, the use of toluene has potential to cause artifacts (Nannipieri et al., 2002), inhibition may not be complete, and amino acids may adsorb to clays and organic matter, which would suggest that this might be a minimum, rather than an actual, proteolysis rate. Additionally, adding a toxin to soil might release free amino acids from the soil biomass, which would elevate the apparent rate. This latter issue would likely be a particular problem in dry soils as bacteria accumulate amino acids as a mechanism to osmoregulate and retain water under dry conditions (Kunte, 2006). This method is also subject to variability and error from free soil amino acids, extraction problems, etc.

The alternative approach to measure proteolysis is to add a known substrate for reaction by soil enzymes. The simplest version of this approach is to add saturating levels of casein or some other protein to a standard "actual" proteolysis assay to determine a potential rate. This approach allows you to evaluate what fraction of the proteolysis potential is actually being met (Weintraub and Schimel, 2005). Protease assays based on the addition of defined low-molecular-weight substrates (i.e., *N*-benzoylargininamide) and product measurement are also commonly used (Ladd and Butler, 1972; Rejsek et al., 2008). A contrasting approach is to add a defined substrate that when reacted produces a colored or fluorescent product (Marx et al., 2001; Saiya-Cork et al., 2002). These assays measure the enzymatic potential or V_{max} under the conditions chosen, not necessarily the process rate in situ. Details for enzyme assays of L-asparaginase, L-glutaminase, amidase, and urease in soil are given in Tabatabai (1994). The arginine ammonification potential has also been used as a laboratory indicator of a soil's ability to process organic N and as a general indicator of the size of the soil microbial biomass (Alef and Kleiner, 1986; Fuller and Scow, 1996). The release of NH_4^+ from arginine is measured in a shaken slurry short-term incubation. This enzyme assay for argininase may be useful as an index for gross mineralization (Bonde et al., 2001). The activity of urease in soil has

been widely studied because urea is a major N fertilizer (most important N fertilizer in world agriculture; Glibert et al., 2006) and because of the substantial inputs of urea from animal wastes. While it is clear that the release of amino acids and other forms of dissolved organic nitrogen (DON) is central to soil organic N turnover; there is no overall consensus on the enzymes or activities that are the best indicators of this depolymerization dynamic.

27.2.3 Biochemistry and Physiology of Immobilization

The incorporation of N into the microbial biomass and soil organic matter occurs via numerous enzymatic and abiotic pathways. This section focuses on the biotic reactions responsible for N assimilation or immobilization. The utilization of soil N includes various steps of extracellular depolymerization or hydrolysis, cell uptake, deamination, and entry into metabolic pathways. Microbes will assimilate both organic and inorganic N sources. Generally, the preferred inorganic N source for assimilation by most bacteria and fungi is NH_3/NH_4^+ although NO_3^- is also used under appropriate conditions (Marzluf, 1997; Myrold and Posavatz, 2007). The uncharged NH_3 may enter microbial cells by rapid diffusion across cytoplasmic membranes. However, specialized ammonia/ammonium transport proteins are widely distributed in archaea, bacteria, and fungi (Merrick and Edwards, 1995; Von Wirén and Merrick, 2004); and genes encoding putative ammonium transport functions are found in many environmental samples (Ogilvie et al., 2008). Intracellular NH_4^+ assimilation by soil microorganisms is predominantly accomplished through the synthesis of glutamate and/or glutamine via two enzymatic pathways: The GS–GOGAT system comprises glutamine synthetase/glutamate synthase (formerly glutamine:2-oxoglutarate aminotransferase hence GOGAT) and GDH pathways (Figure 27.4). The amination of aspartate by ammonium to form asparagine by asparagine synthetase is another possible pathway for assimilation (Hopkins et al., 1995; Barton, 2005). The glutamate and glutamine formed by these pathways serve as central N donors for transamination reactions yielding the amino acids and nucleotides that are the building blocks for proteins and nucleic acids. At the lower NH_4^+ concentrations typical of most soils, the GS–GOGAT system is operative (Schimel and Firestone, 1989; Landi et al., 1995; Paul and Clark, 1996) while GDH pathway functions to immobilizes N under relatively high NH_4^+ concentrations (i.e., >1 mM). The higher affinity GS–GOGAT system requires the input of energy in the form of ATP (White, 2007).

GS plays a central role in the uptake and regulation of N assimilation in soil microorganisms (McCarty and Bremner, 1992a, 1992b; McCarty, 1995). First characterized in the enteric bacteria, the common form of GS (GSI) is composed of 12 identical 55 kDa subunits and is highly conserved in a wide diversity of bacteria. A distinct form of GS (GSII) has been found in *Rhizobium* and *Agrobacterium* (Merrick and Edwards, 1995; Forchhammer, 2007). The NH_4^+ incorporating activity of GS is controlled by covalent modification (adenylation) of the individual subunits, resulting in a range of activity states for

the enzyme. The adenylation of the subunits is controlled by a complex regulatory cascade that senses the intracellular ratio of glutamine to 2-ketoglutarate (Merrick and Edwards, 1995), so that under N sufficiency the enzyme becomes progressively less active. Reviews of global nitrogen regulation (Ntr systems) and N transport in bacteria are given by Merrick and Edwards (1995) and Forchhammer (2007).

GS activity is involved in the regulation of several aspects of N metabolism in soil microbial communities including urease activity and assimilatory nitrate reduction (ANR) (McCarty, 1995). Both urease and ANR are normally repressed in the presence of NH_3/NH_4^+, the preferred N source. McCarty (1995) used an inhibitor of GS, L-methionine sulfoximine (MSX) to show that the production of L-glutamine by GS activity represses these alternative pathways for N utilization. GDH can function bidirectionally to immobilize or mineralize NH_4^+ (Figure 27.4). The direction of catalysis is controlled by N availability, GDH typically functions to immobilize N only under high NH_3 availability due to the relatively high K_m (1 mM) for this enzyme. In *Escherichia coli*, GDH is a hexamer of identical 50 kDa subunits that are encoded by the *gdhA* gene (Merrick and Edwards, 1995).

Nitrate may be immobilized directly by both bacteria and fungi; this process is known as ANR (Paul and Clark, 1996; Myrold and Posavatz, 2007). Energy is required for the transport of NO_3^- across the cell membrane prior to reduction to NH_4^+ by the ANR system. The enzymes responsible for reduction are assimilatory nitrate reductase and assimilatory nitrite reductase (Figure 27.4c). The synthesis of the ANR enzymes, nitrate and nitrite reductases, is regulated by the global Ntr system and inducible by nitrate (Merrick and Edwards, 1995) but repressed by NH_4^+ (Rice and Tiedje, 1989; Recous et al., 1990; McCarty and Bremner, 1992b) or glutamine (McCarty, 1995).

Investigations in soils have shown that both direct assimilation of amino acids (i.e., leucine and glycine) and rapid turnover with subsequent NH_4^+ assimilation can occur in parallel (Barak et al., 1990; Barraclough, 1997; Bardgett et al., 2003; Garnier et al., 2003; Kemmitt et al., 2008). The diverse mechanisms and controls over DON assimilation into the soil microbial biomass is a subject for current investigation (Jones et al., 2004; Schimel and Bennett, 2004; Kemmitt et al., 2008; Manzoni et al., 2008; Myrold and Bottomley, 2008).

27.2.4 Diversity of Enzymatic Functions

The most common ways of studying MIT processes have been through enzyme assays, quantifying nutrient pools, and measuring transformation rates (Kelly, 2003). Such studies have increased our understanding of the role of microbes in regulating these processes but do not give a complete view of the complexity of microbial contributions to soil function (Zak et al., 2006). Specific enzyme activities (such as urease, glutaminase, and protease activity) do not identify the microbial species directly involved in the measured process, leaving the link between the composition of the microbial community and the production of key enzymes poorly understood (Nannipieri et al., 2003; Colloff et al., 2008; Wallenstein
FIGURE 27.4 Major nitrogen assimilation pathways in bacteria. (a) The high affinity (<1 mM) assimilation of ammonia via the glutamine synthetase–glutamate synthase enzymes, (b) low affinity (>1 mM) reversible glutamate dehydrogenase system (From Paul, E.A., and F.E. Clark. 1996. Soil microbiology. Academic Press, San Diego, CA.), and (c) ANR via nitrate binding and transport, nitrate reduction (nitrate reductase), and nitrite reduction (nitrite reductase). (From White, D.C. 2007. The physiology and biochemistry of prokaryotes. 3rd edn. Oxford University Press, New York.)

and Weintraub, 2008). Metagenomic studies in soil environments and the availability of complete genome sequences for microorganisms have revealed a vast genetic diversity of enzyme-encoding genes for the enzymatic processes involved in MIT. The BRENDA searchable database (Chang et al., 2009) is an extensive resource for linking enzymes to their functions, protein sequences, and literature citations. Molecular tools are being developed targeting some of the key enzymes in MIT. For example, extracellular peptidases from proteolytic bacteria were the targets for a study detecting genes in isolates and from soil DNA (Bach et al., 1999, 2001; Bach and Munch, 2000). PCR primers and probes were developed for subsets of the neutral and alkaline metallopeptidases and subtilisin peptidases (Bach et al., 2001). Recent progress in characterizing the diversity of the urease-encoding genes and peptides in

important soil bacteria has allowed these genes to be amplified from DNA extracted from the soil and groundwater (Koper et al., 2004; Gresham et al., 2007). The diversity of the serine proteases (i.e., trypsin) in fungi has been examined for a broad range of cultured fungi (Hu and Leger, 2004) and this analysis may form the basis for targeting subsets of genes encoding fungal enzymes involved in depolymerization. Functional gene microarrays such as the GeoChip, contain >24,000 oligonucleotide probes covering >10,000 genes in >150 functional groups involved in nitrogen, carbon, and sulfur cycling, metal reduction and resistance, and organic contaminant degradation (He et al., 2007). Over 1400 of these were related to N mineralization functions. The most recent version of this microarray contains over 70,000 gene variants in more than 400 functional categories (Zhou et al., 2010) with comparatively

more probes related to MIT processes. Understanding the diversity of organisms responsible for any specific MIT process active in the environment will require further ecophysiological investigations to complement these emerging molecular tools.

27.2.5 Substrate Quality Effects on Mineralization–Immobilization Turnover

Substrates for decomposition vary in their chemical constitution and complexity. These differences affect the rate at which microorganisms process the material and the amount of N that is required or released during microbial growth on the substrate. The substrates, which are decomposed, include both materials that are inputs to the soil such as plant debris, animal manure, and industrial wastes and those that are internal to the soil system such as soil organic matter and microbial decay products. The availability of the substrate for decomposition, the efficiency with which microbes assimilate organic carbon into biomass (substrate use efficiency or yield coefficient), and the C/N ratio of the microbial biomass determine the requirement for N during substrate decomposition (Janssen, 1996; Myrold and Bottomley, 2008). If excess N is present in the substrate relative to the microbial demand, then net N mineralization will result, conversely when the N required by microorganisms is greater than that present in the substrate then microorganisms will immobilize inorganic N from the soil solution or slow their growth and have a widened C/N ratio until N becomes available. While the actual situation during decomposition is extremely complex with numerous fractions of various composition and availability, there is a history of the use of simple characteristics as indicators for substrate quality and in estimation of the N demand during decomposition (Janssen, 1996; Myrold and Bottomley, 2008). Table 27.2 gives some representative C/N ratios for various organic materials and Figure 27.5 shows the relationship between the critical C/N ratio, microbial C/N ratio, and the

FIGURE 27.5 Model of the critical C/N ratio of substrates that results in no net mineralization of nitrogen with different microbial C yield coefficients and C/N ratio of the microbial biomass produced. (After Myrold, D.D. and Bottomley, P.J., Nitrogen mineralization and immobilization, in: W. Raun and J.S. Schepers (eds.), *Nitrogen in Agricultural Soils*, ASA, Madison, WI, pp. 157–172, 2008.)

microbial yield coefficient. Generally, substrates with C/N ratios less than 20/1 or N contents greater than 1.5% N result in net N mineralization while those higher than 30/1 or with N contents less than 1.5% tend to immobilize soil inorganic N. This oversimplification does not represent complex substrates with large proportions of resistant materials such as lignin; these materials may mineralize N at C/N ratios up to 50/1 due to the differential decay rates for distinct fractions of the material (Paul and Clark, 1996; Myrold and Bottomley, 2008). As decomposition of a substrate proceeds, the C/N ratio of the material remaining in the soil (a combination of the remaining substrate and the microbial products) will decrease and N will eventually be mineralized.

Models of C and N turnover in soil have often used the lignin to N ratio of the substrate as an indicator of substrate quality (Melillo et al., 1982; Parton et al., 1987, 1988; Cabrera et al., 2008). Substances with high lignin to N ratios are considered to have more structural materials, which degrade more slowly, with lower microbial efficiencies (Paustian et al., 1992). In contrast, some recent studies did not find the lignin to N ratio to be correlated to decomposition or N mineralization from soils amended with a variety of plant materials (Jensen et al., 2005; Bruun et al., 2006). Particularly when materials contain substantial amounts of other complex polyphenolics, such as tannins, the lignin:N ratio may be inadequate as an indicator of decomposition and mineralization patterns. Simulation models of MIT are further discussed in Section 27.2.7.

One important substrate for mineralization is the microbial biomass itself. Predators and grazers (protozoa, nematodes, etc.) may consume large amounts of bacteria and fungi with relatively low C/N ratios and therefore these consumers subsequently excrete substantial amounts of N (Clarholm, 1985; Coleman et al., 2004). Protozoa and microphagous nematodes are important grazers of microflora in the belowground ecosystems and generally increase microbial turnover, promote N mineralization, and may change the composition of the microbial community (Bonkowski et al., 2000;

TABLE 27.2 Approximate C/N Ratios in Various Organic Materials

Organic Material	C/N Ratio
Soil microorganisms	8/1
Soil organic matter	10/1
Sewage sludge	9/1
Alfalfa residues	16/1
Farmyard manure	20/1
Corn stover	60/1
Grain straw	80/1
Oak	200/1
Pine	300/1
Crude oil	400/1
Conifer sawdust	625/1

Raynaud et al., 2006). The complex belowground food webs and the importance of the microbial loop are discussed in Chapter 26.

27.2.6 Process Rates and Kinetics

The rate and extent of MIT reactions determine the availability of N to plants and the potential for N losses for many ecosystems. However, because the amount of inorganic N in the soil is the result of several opposing productive and consumptive processes, our ability to predict its availability remains challenging.

Generally, mineralization is the conversion of organic N to inorganic N while immobilization is the reverse process of assimilation of inorganic N into the biotic biomass and hence organic N. However, in actual use, these terms have several different meanings that are related to how they are determined. The net mineralization rate is the rate of inorganic N accumulation and is equal to the rate of conversion of organic N to NH_4^+/NH_3 and NO_3^- minus their consumption. Net mineralization refers to the case where the inorganic N pool is increasing with time because gross rates of mineralization are higher than rates of combined immobilization plus losses. The gross mineralization rate is the actual rate of conversion of organic N to NH_4^+/NH_3. The gross mineralization rate is also equal to the rate of NH_4^+ accumulation plus the rate of NH_4^+ consumption plus losses. Determining gross rates requires the use of isotopes of N to separate simultaneous production and consumption. The potential mineralization rate is the net rate of mineralization in a soil system with plant uptake and leaching prevented (although the potential rate is operationally defined by the actual method chosen for its determination). Previously, many investigators assumed that measured net mineralization rates in the absence of plant uptake and leaching were adequate indicators of the importance and rate of mineralization in the environment. This assumption neglected the potential role of inorganic N assimilation by microorganisms and denitrification. Significant rates of inorganic N assimilation are often measured simultaneously with net mineralization (Powlson and Barraclough, 1993; Schimel and Bennett, 2004). Net mineralization also neglects the turnover and uptake of simple organic compounds by both plants and microbes, processes that may supply much of the biotic N demand in some ecosystems (Schimel and Bennett, 2004).

Immobilization is defined as the assimilation of inorganic N (NH_4^+/NO_3^-) into the soil organic matter (i.e., microbial biomass). Net immobilization refers to the case where the inorganic N pool is decreasing due to higher gross rates of immobilization than gross rates of mineralization. Net immobilization may also encompass some abiotic processes, such as NH_4^+ fixation into clays, although these rarely appear to be a large fraction of total immobilization. The gross immobilization rate is the actual rate of conversion of inorganic N to organic N. Gross NH_4^+ immobilization is only a portion of the total NH_4^+ consumption that also includes nitrification and plant root uptake. Inorganic N consumption includes NH_4^+ and NO_3^- immobilization by heterotrophic microorganisms, plant root uptake, nitrate leaching, denitrification, ammonia volatilization, and dissimilatory nitrate reduction to ammonia (DNRA) as well as abiotic reactions of NH_3 and NO_2^- with organic matter.

The distinction between total consumption of inorganic N, NH_4^+ consumption and immobilization becomes particularly important in the determination of gross immobilization rates.

27.2.6.1 Measurements of Mineralization and Immobilization Rates

Numerous measurements of soil mineralization rates have been made in ecosystems throughout the globe, the majority of measurements are net rates; fewer estimates are available for gross mineralization/immobilization rates on undisturbed soil cores (Murphy et al., 2003; Booth et al., 2005). The basic principles and application of N isotopes for determination of gross mineralization and immobilization rates in soils were developed several decades ago (Kirkham and Bartholomew, 1954, 1955; Jansson, 1958) but innovations in mass spectrometry including direct combustion isotope ratio mass spectrometry (Hauck et al., 1994; Mulvaney, 2008) made the use of ^{15}N for estimating gross rates more accessible. Determining NH_4^+, NO_2^-, and NO_3^- concentrations in soils (Bundy and Meisinger, 1994; Hart et al., 1994b) is the starting point for almost all the rate measurements described as follows. Soil should be extracted as soon as possible after sampling as inorganic N levels change rapidly in disturbed samples. The following discussion is focused on methods for determining mineralization and immobilization rates, starting from the simpler laboratory measurements of net mineralization progressing to the field measurements of gross mineralization and immobilization rates. Investigators should consider carefully the justification for using the more complex and expensive determination of gross rates of N transformations unless the goal is to understand the controls and activity of soil microorganisms (Murphy et al., 2003).

27.2.6.1.1 *Laboratory Methods for Net and Potential Mineralization Rates*

Laboratory incubation experiments have a long history of being used to examine net mineralization in the absence of plant uptake and under conditions that minimize gaseous and leaching losses (Standford and Smith, 1972). These experiments give an estimate of the mineralizable N pool and are most useful as indices of the N supplying potential of closely related soils or a soil that has received various amendments or treatments (Griffin, 2008). The basic premise to all the laboratory incubation methods is that initial soil inorganic N determinations are made, the soil is incubated under a defined temperature, and moisture regime and the amount of inorganic N produced during a specified time period are determined. Typically, the soils are sieved and homogenized before incubation; however, intact cores may be more easily related to field mineralization rates (Cabrera and Kissel, 1988). The artificial conditions of constant temperature and controlled moisture and the reliance on net rates minimize the relation of mineralization potential measurements to gross mineralization rates in the field (Stark, 2000). Many variations of the laboratory incubation method are described in the literature (Hart et al., 1994b), the various methods may give contrasting results with different soils (Benbi and Richter, 2002). Interpretations may involve modeling of the time course of released inorganic N to

determine the pool size of the mineralizable or labile N according to various models (most typically, first-order rates). Recent analyses using simulation modeling more realistically represents mineralizable N as several pools with different mineralization rates (Ma and Shaffer, 2001; Benbi and Richter, 2002).

27.2.6.1.2 Field Measurements of Net Mineralization

Several methods are available for determining net mineralization and nitrification in the field; all include a barrier to prevent root uptake of NH_4^+ and NO_3^- and to prevent or capture the NO_3^- in the mass flow of water. The buried bag and soil core methods are described as suitable procedures for field estimates of net mineralization (Hart et al., 1994b). Typically intact soil cores are used to minimize disturbance artifacts (i.e., increased mineralization) caused by sieving and mixing, but this approach increases the number of replicates needed to encompass site variability (Hart et al., 1994b). Both the buried bag and the solid core method may alter the moisture status of the soil inside the container as compared to the external soil (Griffin, 2008). In solid core methods, soil is incubated intact inside PVC or steel cylinders either with the top covered to prevent water entry or opened but with the bottom of the core containing a ring filled with mixed bed ion exchange resin to catch leachate (Hart et al., 1994b). Although net mineralization rates have been related to N loss from forest ecosystems and plant available N in agroecosystems, they may not be well correlated to gross rates of N processes (Davidson et al., 1992; Hart et al., 1994a).

27.2.6.1.3 Gross Rates of Mineralization and Immobilization: The Use of Isotopes

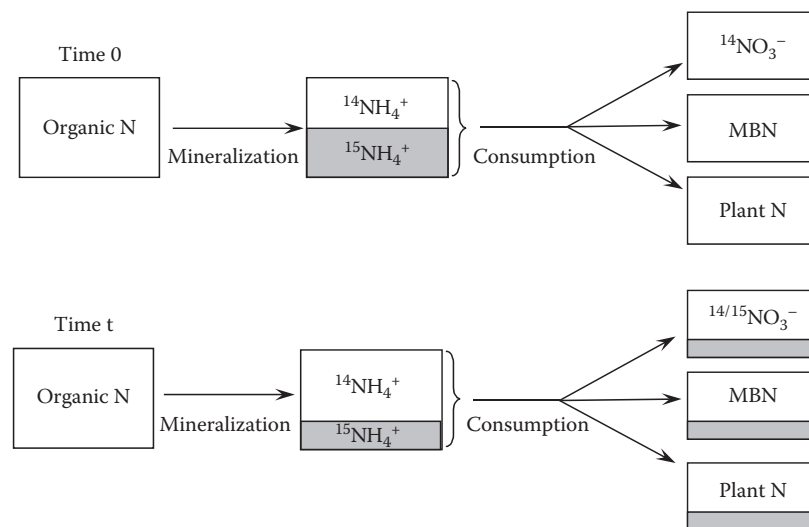
The measurement of actual or gross rates of mineralization and immobilization requires the use of isotopes of N, the stable isotope ^{15}N is used almost exclusively because the radioactive isotope, ^{13}N has an extremely short half-life (~10 min) that is not conducive for ecological studies. In general, ^{15}N can be used in two contrasting approaches to examine MIT: (1) tracer methods in which ^{15}N is added as the substrate for the process of interest and (2) pool dilution methods in which ^{15}N is added to the product pool of the transformation of interest. Mineralization rates have been assessed by tracer techniques in which ^{15}N-labeled plant material or other ^{15}N organic substrates are added to the source pool and the fate of the added ^{15}N is monitored. In the pool dilution approach, ^{15}N is added and the dilution of its enrichment by the production of $^{14}NH_4^+$ by mineralization is monitored over time. Immobilization rates may be estimated by the tracer method or by a combination of the isotope dilution and tracer techniques. The tracer approach for mineralization involves the preparing and using ^{15}N-labeled organic substrates and allows the investigator to assess the mineralization potential of the material and follow the fate of the added ^{15}N. The data from these studies are particularly useful for parameterizing simulation models of MIT. Methods for labeling plants and the microbial biomass with ^{15}N are described by Wolf et al. (1994) and the preparation of organic materials for analysis is described (Hauck et al., 1994). The tracer approach for estimating immobilization rates involves adding $^{15}NH_4^+$ or $^{15}NO_3^-$ and then measuring the appearance of ^{15}N in the sink pool, usually the microbial biomass or soil organic matter (Powlson and Barraclough, 1993). In N-limited systems, the addition of substrate may stimulate microbial assimilation and therefore overestimate immobilization rates (Hart et al., 1994b). The tracer approach is particularly useful for estimating immobilization rates in the presence of several consumptive processes (i.e., plant uptake, nitrification, ammonia volatilization) and is often used in combination with the pool dilution approach described below to answer mechanistic questions on MIT (Schimel et al., 1989; Norton and Firestone, 1996)—when you add $^{15}NH_4^+$ to the soil for a pool dilution study, you can also use it as a tracer for measuring flows into NO_3^-, microbial biomass, and plants (Figure 27.6).


FIGURE 27.6 Combined pool dilution and tracer approach for estimation of mineralization and immobilization rate. At the beginning of incubation (time 0) $^{15}NH_4^+$ is added and initial pool sizes and enrichments are determined. At end of the incubation (time t) the final pool sizes and enrichments are determined. The mineralization and NH_4^+-consumption rates are determined by pool dilution calculation, NH_4^+ immobilization rate determined by tracer analysis. Assumptions include that there is no recycling within the time of the incubation.

The pool dilution approach for estimating mineralization and NH_4^+ consumption rates has been used for numerous laboratory and field studies (Murphy et al., 2003; Booth et al., 2005; Hooker and Stark, 2008). The pool dilution approach is ideally suited for measurements of gross mineralization rates, but the estimates of NH_4^+ immobilization are less reliable because adding the $^{15}NH_4^+$ substrate may stimulate uptake and there are several additional processes that consume NH_4^+. Nitrification, frequently the largest consumptive process, may be determined from parallel NO_3^- pool dilution experiments or nitrification may be blocked using acetylene. Plant uptake can be calculated from the ^{15}N content of the plant tissue or blocked by preventing root uptake with a barrier method. Ammonia volatilization, which is important only in alkaline soils, can be measured by including an acid trap for the volatilized NH_3 in the experiment or calculated by difference. It is recommended that total recoveries of ^{15}N in the plant–soil system be determined to detect any unexplained loss of ^{15}N. The specific recommendations for sampling and techniques for field pool dilution experiments in intact cores without plants are discussed and background and calculations for estimating mineralization and assimilation in the plant–soil system are given (Davidson et al., 1991; Hart et al., 1994b; Stark, 2000; Murphy et al., 2003). Representative rates of NH_4^+ production and consumption determined by pool dilution from agricultural and wildland ecosystems have been reviewed (Booth et al., 2005).

27.2.7 Simulation Models of Mineralization–Immobilization Turnover

Kinetic and simulation models of nitrogen turnover in the plant–soil system can be useful for understanding the interactions of the multiple processes involved. Often the combination of experimental and modeling approaches provides a synthesis and identifies gaps in our knowledge. When models fail to adequately express the realities of the observed system this is often the first step toward understanding of a neglected process. An example is the identification of the importance of simultaneous microbial immobilization and mineralization for simulating short-term inorganic N dynamics and the role of soil heterogeneity (Manzoni et al., 2008). Nitrogen process models have become more crucial for predicting NO_3^- leaching after application of organic materials and mineral fertilizers; it is no longer sufficient to predict plant needs and economic returns, environmental impacts of excess N must be considered. Regional and global carbon models require information on N availability and the potential for N to limit carbon sequestration.

Existing models vary in the number of organic matter pools represented and their definition, the number of distinct pools involved in MIT, the role of the microbial biomass and its turnover, and whether nitrification and denitrification are considered. In general, most models link the cycling of N to the C cycle processes with C availability controlling microbial biomass growth and turnover (Paustian et al., 1992; Cabrera et al., 2008). Current N turnover models have been critically reviewed and compared for their treatment of the above factors. A general consensus is that improved submodels dealing with the maintenance and growth of the microbial biomass and particularly seasonal variation in the microbial biomass N are needed to adequately predict inorganic N dynamics (Ma and Shaffer, 2001; Cabrera et al., 2008). While our conceptual models and the computer simulations of MIT in soils may never fully converge, the process of quantitatively formulating the complex processes in the soil environment improves our predictive ability and identifies our misconceptions.

27.2.8 Concluding Remarks

The nitrogen cycle is the global biogeochemical cycle that humans have most dramatically perturbed—industrial N fixation is now roughly equivalent to total natural fixation (Vitousek et al., 1997; Schlesinger, 2009). This perturbation has resulted in eutrophication of waterways, dead zones in coastal waters, an enhanced greenhouse effect, and local smog production. Managing N cycling in the future to minimize these adverse impacts, while optimizing food, fuel, and fiber production is likely to require a more sophisticated understanding of the processes that impact N availability and transport. Mineralization is the most critical process, as it regulates plant uptake, nitrification, leaching, and trace gas emissions. Yet, MIT is inherently complex because it is a web of processes involving every organism in the soil. It couples the activity of extracellular enzymes, microbial metabolism and growth, food web dynamics, and the physical structuring of these processes within the soil matrix. Our current ability to effectively model this interaction remains crude and inadequate for many situations because there are many cases where the simplifying assumptions of biogeochemical models do not match the reality of the soil. We need new models that more effectively capture the complex dynamics of mineralization but do so in a way that does not require modeling all the specific components directly—such models would be excessively unwieldy. Understanding the role of functional redundancy in the enzymes and biota will be essential to our perception of system function. To reach this new level in modeling N mineralization, we need a more integrated understanding of how all the processes of mineralization interact to regulate the overall turnover of organic and inorganic N in soils. Nitrogen mineralization and immobilization process many times the net inputs and outputs of inorganic N from the soil system. Identification of the controlling factors on the individual processes (Booth et al., 2005), not their combined outcome, will be necessary to develop an improved mechanistic understanding of nitrogen flow through the soil ecosystem.

27.3 Nitrification

James I. Prosser

27.3.1 Introduction

Nitrification is the microbial oxidation of reduced forms of nitrogen to nitrate. Most nitrification in soil is carried out by autotrophic ammonia and nitrite oxidizers, sequentially converting ammonia to nitrite and nitrate. Heterotrophic nitrifiers oxidize organic forms of reduced nitrogen, for example, amines to nitrate. The major sources of soil ammonia are mineralization of organic matter, animal excreta, and two anthropogenic sources of increasing importance: nitrogen fertilizers and atmospheric nitrogen deposition, supplying 100 and 25 Tg N year^{-1}, respectively (Gruber and Galloway, 2008). Whereas NH_4^+ is held within the soil, due to the predominance of negatively charged particulate material, NO_3^- is readily leached from the soil. Nitrification is therefore important in controlling the levels of ammonium and nitrate available for plant growth and losses of fertilizer nitrogen, which can lead to polluting levels of nitrate in groundwaters. Within the soil, nitrate is also lost through denitrification to nitrogen and the greenhouse gas nitrous oxide, which is generated by both nitrifiers and denitrifiers.

27.3.2 Nitrifying Microorganisms

Autotrophic ammonia oxidation is carried out by four microbial groups, three within the *bacteria*, the betaproteobacteria, gammaproteobacteria, planctomycetes, and a group within the *archaea*.

27.3.2.1 Autotrophic Ammonia-Oxidizing Bacteria

27.3.2.1.1 Phylogeny

Phylogenetic analysis of 16S rRNA gene sequences places cultivated autotrophic ammonia oxidizers from soil in seven lineages within the betaproteobacteria (Table 27.3). Six are within the genus *Nitrosomonas* and the seventh, *Nitrosospira*, is further subdivided into five "clusters," although this subdivision is less phylogenetically robust and is based, partly, on sequences amplified directly from environmental DNA, rather than pure cultures. The gammaproteobacterial *Nitrosococcus oceanus* appears to be restricted to marine environments. Phylogeny based on the *amoA* gene (encoding ammonia monooxygenase subunit A) is generally congruent with 16S rRNA gene phylogeny. Two groups, *Nitrosomonas*

TABLE 27.3 Phylogenetic Affiliations and Environmental Origin of Isolates and Environmental Sequences of Autotrophic Ammonia- and Nitrite-Oxidizing Bacteria and Ammonia-Oxidizing Archaea

Ammonia Oxidizers	Lineage	Environmental Origin of Isolates (Where Available) and Sequences
Betaproteobacteria	*Nitrosomonas europaea*/*Nitrosococcus mobilis*	Soil, freshwater, marine, wastewater
	Nitrosomonas communis	Soil, freshwater, marine, wastewater
	Nitrosomonas oligotropha	Soil, freshwater, wastewater
	Nitrosomonas marina	Marine, freshwater
	Nitrosomonas cryotolerans	Marine
	Nitrosomonas sp. Nm143	Marine
	Nitrosomonas environmental lineage 5	Soil, freshwater, marine, wastewater (no isolate)
	Nitrosospira "Cluster 0"	Soil, freshwater
	Nitrosospira "Cluster 1"	Soil, marine (no isolate)
	Nitrosospira "Cluster 2"	Soil, freshwater, wastewater
	Nitrosospira "Cluster 3"	Soil, freshwater, wastewater
	Nitrosospira "Cluster 4"	Soil, freshwater
Gammaproteobacteria	*Nitrosococcus*	Marine
Planctomycetes	"Anammox" organisms	Marine, wastewater
Archaea	Crenarchaeal Group 1.1a	Soil and marine (no soil isolate)
	Crenarchaeal Group 1.1b	Soil (no isolate)
	Crenarchaeal Group 1.1a-associated	Soil (no isolate)
Nitrite Oxidizers		
Alphaproteobacteria	*Nitrobacter*	Soil, freshwater
Betaproteobacteria	*Candidatus Nitrotoga arctica*	Soil
Nitrospirae	*Nitrospira*	Soil, freshwater, soil
Gammaproteobacteria	*Nitrococcus*	Marine
Nitrospina	*Nitrospina*	Marine

environmental lineage 5 and *Nitrosospira* "Cluster 1," have no known cultivated representative.

Bacterial ammonia oxidizers are Gram negative. Phenotypically they are distinguished in terms of cell morphology, presence, and location of intracytoplasmic membranes (the site of ammonia oxidation) and inclusion bodies (including carboxysomes, the site of CO_2 fixation) and physiological characteristics, including urea hydrolysis, salt tolerance, and affinity for and inhibition by ammonia. Some links exist between phylogenetic groups and these phenotypic characteristics (Koops and Pommerening-Röser, 2001), but classification and identification are now routinely based on analysis of 16S rRNA or *amoA* gene sequences. Most physiological studies have been carried out on *Nitrosomonas europaea* but complete genomes of several bacterial ammonia oxidizers have been sequenced, allowing analysis of evolutionary relationships and physiological potential (Klotz and Stein, 2008). There is, however, a need for physiological characterization of a wider range of bacterial ammonia oxidizers, and for the use of techniques enabling analysis of in situ physiology, to assess physiological characteristics, and potential ecosystem function of different phylotypes.

27.3.2.1.2 Biochemistry

Soil bacterial ammonia oxidizers are chemolithoautotrophs, gaining energy by oxidation of ammonia (NH_3 rather than NH_4^+), via hydroxylamine, to nitrite. The first step is endergonic, requires oxygen and a source of reducing equivalents and is catalyzed by a membrane-bound ammonia monooxygenase:

$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O. \qquad (27.2)$$

Ureolytic ammonia oxidizers can grow on urea, generating ammonia within the cell by urease activity following urea uptake. The second step, oxidation of hydroxylamine to nitrite, generates reducing equivalents, is catalyzed by hydroxylamine oxidoreductase, and uses oxygen from water:

$$NH_2OH + H_2O \rightarrow NO_2^- + 5H^+ + 4e^-. \qquad (27.3)$$
Two electrons are used in the first step, for ammonia oxidation, and the remaining two pass down the electron transport chain. NADH is synthesized by reverse electron flow, as the NO_2^-/NH_3 redox potential is only $-340\,mV$. Generation of H^+ leads to acidification, which eventually limits continued growth in liquid culture and in soil. Arp and Stein (2003) provide further details of the biochemical mechanisms involved in ammonia oxidation.

Ammonia oxidizers are autotrophs, obtaining organic carbon by carbon dioxide fixation and possess Type I Rubisco genes. This creates a demand for reducing equivalents, which are generated by reverse electron flow, consuming ATP. Consequently, the energy generated by oxidation of ammonia to nitrite is barely sufficient to support growth. An ammonia oxidizer must convert approximately 10 times its own weight of ammonia to double in size. Growth yields are therefore low and ammonia oxidizers have low growth rates, with minimum doubling times for

laboratory strains of approximately 8 h. Autotrophic bacterial ammonia oxidizers can assimilate organic carbon, for example, acetate, formate, and pyruvate, potentially increasing growth yield; but heterotrophic growth is not possible. In addition, the ammonia monooxygenase enzyme can oxidize a range of polluting organic compounds, including butane, bromoethane, benzene, ethylbenzene, chlorobenzene, and naphthalene (Arp and Stein, 2003). Ammonia oxidizers may therefore contribute to remediation in oligotrophic soils.

Soil ammonia oxidizers and methanotrophs are not closely related phylogenetically, but ammonia and methane monooxygenases can oxidize both ammonia and methane and are inhibited by similar compounds. Neither functional group can grow on the substrate of the other and ammonia oxidizers have much lower affinity and specific activities for methane oxidation than methanotrophs. There is, however, evidence for competitive inhibition, which may reduce methane oxidation in heavily fertilized soils. Ammonia oxidizers also have greater affinity for carbon monoxide than cultivated carboxydobacteria and may contribute to oxidation of this greenhouse gas.

Ammonia oxidizers produce nitrous oxide through chemical decomposition of intermediates during hydroxylamine conversion to nitrite and through nitrifier denitrification. The latter process involves sequential reduction of nitrite to nitric and nitrous oxides and nitrogen gas (Wrage et al., 2001; Stein and Yung, 2003). Functional genes encoding nitrite, nitrous oxide, and nitric oxide reductases are present in all *Nitrosomonas* and *Nitrosospira* strains investigated, are less well conserved than *amoA* genes, and may have been subject to lateral gene transfer (Cantera and Stein, 2007; Garbeva et al., 2007). Nitrous oxide production increases with decreasing oxygen concentration and is typically equivalent to around 1% of nitrite produced (Jiang and Bakken, 1999b; Garbeva et al., 2007). Technical restrictions in distinguishing nitrous oxide production by denitrifiers and nitrifiers make it difficult to estimate the contribution of ammonia oxidizers, but there is evidence that up to 80% of total soil N_2O is produced by ammonia oxidizers under some conditions (Wrage et al., 2005) and production increases following addition of artificial urine (Wrage et al., 2004a) and ammonium (Avrahami et al., 2002).

Ammonia oxidation can also occur under anaerobic conditions by two processes, although neither has been reported in soil. The first, the anammox process, is common in marine environments and wastewater treatment plants, is carried out by planctomycetes and involves the generation of nitrate and nitrogen using nitrite as an electron acceptor, with hydrazine and hydroxylamine as intermediates:

$$NH_4^+ + 1.32NO_2^- + 0.066HCO_3^- + 0.13H^+$$

$$\rightarrow 0.26NO_3^- + 1.02N_2 + 0.066CH_2O + 0.5N_{0.15} + 2.03H_2O$$

$$(27.4)$$
The second, reported in laboratory cultures of *Nitrosomonas eutropha*, involves use of nitrogen dioxide or nitrogen tetroxide as an electron acceptor, generating hydroxylamine and nitric

oxide, which is then converted to nitrite and dinitrogen gas (Schmidt et al., 2002):

$$NH_3 + N_2O_4 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O + 2NO \quad (27.5)$$

$$NH_2OH + H_2O \rightarrow HNO_2 + 4H^+ + 4e^- \quad (27.6)$$

$$NH_3 + N_2O_4 \rightarrow HNO_2 + 2NO + 2H^+ + 2e^- \quad (27.7)$$

$$HNO_2 + 3H^+ + 3e^- \rightarrow 0.5N_2 + 2H_2O. \quad (27.8)$$
Nitric oxide can stimulate growth, activity, and cell yield and reduce the lag phase, providing potential benefits in soil, where ammonia supply is likely to be intermittent.

Although both processes are anaerobic, they require substrates produced under oxic conditions and may therefore be important at oxic–anoxic interfaces within the soil, in biofilms, or in regions alternating between oxic and anoxic conditions.

27.3.2.2 Autotrophic Ammonia-Oxidizing Archaea

There is increasing evidence that archaea contribute to soil ammonia oxidation, following the discovery of putative *amoA* and *amoB* genes and a 16S rRNA gene representative of the crenarchaeal Group 1.1b sublineage on a soil metagenome fragment (Treusch et al., 2005). The potential for archaeal ammonia oxidation was confirmed by the isolation, from a marine aquarium, of a crenarchaeal, chemolithoautotrophic NH_3 oxidizer, "*Candidatus Nitrosopumilus maritimus*" (Könneke et al., 2005). This strain is mesophilic, belongs to the crenarchaeal Group 1.1a lineage, possesses *amoA* and *B* sequences similar to those from metagenome studies, and has growth characteristics similar to those of bacterial ammonia oxidizers. No soil crenarchaeal ammonia oxidizer has yet been isolated, but crenarchaeal *amoA* genes can be amplified from all soils investigated and are frequently more abundant than bacterial *amoA* genes. Evidence for the relative contributions of bacteria and archaea to soil ammonia oxidation is reviewed in Prosser and Nicol (2008).

27.3.2.3 Autotrophic Nitrite Oxidizers

Nitrite-oxidizing bacteria fall within five phylogenetic groups (Table 27.3), three of which are represented in soil. *Nitrobacter* belongs to the alphaproteobacteria, possesses intracytoplasmic membranes, and is related to photosynthetic bacteria. *Nitrospira* belongs to the deltaproteobacteria, does not contain intracytoplasmic membranes, and is rarely found in soil enrichment cultures. The third group is represented by a single isolate, "*Candidatus Nitrotoga arctica*," recently isolated from an Arctic soil and belonging to the betaproteobacteria (Alawi et al., 2007). Two other groups, *Nitrococcus* (gammaproteobacteria) and *Nitrospina*, have not been detected in soil. Nitrite oxidation is catalyzed by nitrite oxidoreductase, with oxygen supplied by water:

$$NO_2^- + H_2O \rightarrow NO_3^- + 2H^+ + 2e^- \quad (27.9)$$
The NO_3^-/NO_2^- redox potential is $-430\,mV$ and, as for ammonia oxidizers, reducing equivalents are generated by reverse electron flow, consuming ATP. Autotrophic growth occurs at rates similar to those of autotrophic ammonia oxidizers. However, nitrite oxidizers range from autotrophs to mixotrophs and heterotrophs, growing on low-molecular-weight organic substrates. Heterotrophic growth is much slower, with doubling times of 30–150 h, but with higher biomass yield, and this may partly explain their greater abundance in soil. Nitrite oxidation to nitrate is effectively a reversible process and, under anaerobic conditions, nitrite oxidoreductase enables use of nitrate as an electron acceptor during anaerobic heterotrophic growth. Nitrite oxidizers can therefore also denitrify and contribute to production of nitrogen oxides. Biochemical studies have focused on *Nitrobacter* because of its ease of isolation and faster growth in laboratory culture. However, growing realization of the environmental importance of nitrospiras, targeted isolation of new strains, and genomic studies are increasing our understanding of the biology of nitrite oxidizers (Starkenburg et al., 2006, 2008; Maixner et al., 2008).

27.3.2.4 Heterotrophic Nitrification

Heterotrophic nitrification is the oxidation of inorganic and organic reduced forms of nitrogen to nitrite or nitrate during heterotrophic growth of fungi or bacteria. Heterotrophic nitrification does not contribute to growth or energy production and specific rates of heterotrophic nitrification are much lower than autotrophic nitrification. Nevertheless, there is evidence for its importance in acidic soils, including forest soil, where autotrophic ammonia oxidizers are inhibited or at low abundance (De Boer and Kowalchuk, 2001). In some organisms, heterotrophic nitrification operates with similar mechanisms to autotrophs, while "fungal nitrification" involves reaction of reduced organic compounds with hydroxyl radicals, produced in the presence of hydrogen peroxide and superoxide, and is linked to lignin degradation.

27.3.2.5 Cultivation and Isolation of Nitrifying Bacteria

Ammonia- and nitrite-oxidizing bacteria are cultivated in liquid mineral salts medium containing ammonium or nitrite, respectively. Growth is assessed by qualitative or quantitative changes in substrate and/or product concentrations. Growth of ammonia oxidizers is also determined by inclusion of a pH indicator in the growth medium (typically phenol red) to detect production of acid. Cultures are susceptible to contamination by heterotrophs, which generally grow faster, making purification difficult. Nitrifiers form only microscopic colonies on solid medium after incubation for many weeks, making purification from isolated colonies difficult, while purification by endpoint dilution methods requires very low levels of inoculation of fresh medium. Isolates are usually maintained as live cultures, in addition to preservation in liquid nitrogen or in a freeze-dried state because of poor survival and induction of very long lag phases during resuscitation.

It is becoming increasingly feasible to determine the physiological in situ activity of specific nitrifier phylotypes using cultivation-independent, molecular methods in association with

stable isotope probing, radiolabeling and associated techniques (Freitag et al., 2006; Hatzenpichler et al., 2008). Nevertheless, analysis of pure cultures remains an important tool in understanding the ecology and functional diversity of soil nitrifiers, for comparative genomics and for validation of molecular techniques. Soil archaeal ammonia oxidizers have yet to be isolated, but nitrifying soil bacteria can be enriched by inoculation of appropriate mineral salts medium with a soil suspension and incubation for several weeks. The use of inorganic medium reduces but does not prevent growth of heterotrophic contaminants, even with successive subculturing. Heterotrophs grow on by-products of nitrifier growth but also on organic contaminants of culture vessels and volatile organic compounds. Contamination may therefore be reduced by oven heating or acid washing of glassware and sealing of flasks, while ensuring adequate supply of oxygen (Aakra et al., 1999). Isolation of pure cultures is much more difficult, typically takes several months, due to slow growth of nitrifiers, and cultures frequently die with continued subculturing. Laboratory enrichment is likely to select for fast growing strains, but soil isolates often exhibit very low growth rates, making maintenance and physiological characterization difficult. Enrichment of strains that are representative of natural soil communities is now made easier by molecular analysis of enrichment cultures to identify dominant community members (Smith et al., 2001). Ammonium concentration in enrichment media is also important, as high ammonium concentration can be inhibitory.

27.3.2.6 Enumeration of Nitrifiers

The microscopic size of nitrifier colonies on solid media and difficulties in eliminating heterotrophs prevent viable cell enumeration by plate counting and necessitate the use of the most probable number (MPN) method. A dilution series (typically 10-fold) of a soil suspension is used to inoculate, in replicate for each dilution, liquid mineral salts medium containing ammonium or nitrite and (for ammonia oxidizers) a pH indicator. Growth is assessed qualitatively after incubation (typically for 4 weeks) and statistical tables or software programs are used to estimate cell abundance. The method is limited by requirement for laboratory growth and selection of different ammonia oxidizers at different ammonium concentrations (Phillips et al., 2000a). In addition, the number of tubes showing growth increases with increasing incubation time (Matulewich et al., 1975) and intrinsic errors result from the requirement for statistical estimation of cell number. The highest MPN dilutions exhibiting growth can, however, be used for enrichment and isolation, to increase the probability of obtaining representatives of dominant soil organisms.

The limitations of MPN enumeration can be avoided by use of PCR-based, molecular methods for quantification of diagnostic genes. Competitive PCR has been used to quantify bacterial ammonia oxidizer 16S rRNA genes (Phillips et al., 2000b; Hermansson et al., 2004) and real-time PCR for quantification of 16S rRNA and *amoA* genes (Okano et al., 2004; Leininger et al., 2006; Nicol et al., 2008). qPCR methods do not distinguish living, dead, and dormant cells and are subject to biases (Smith et al., 2006), including those common to all molecular methods. In addition, they may overestimate abundance of organisms with multiple copies of the target gene within the chromosome, and gene copy number will depend on growth rate and position on the chromosome.

Nevertheless, qPCR is rapidly becoming the standard method for enumeration of nitrifiers in environmental samples because of its ability to detect, and quantify, unculturable organisms. Phillips et al. (2000a) found that MPN counts were typically 1–2 orders of magnitude less than molecular estimates of abundance, based on qPCR of 16S rRNA genes (Figure 27.7). Molecular analysis of positive MPN tubes also indicated selection of nitrosomonads in medium with higher ammonium concentrations.
FIGURE 27.7 Abundance of bacterial ammonia oxidizers in long-term ecological research plots subjected to different management regimes. Viable cell concentration was determined using the MPN method with medium containing 5, 50, or 1000 mg NH_4^+–N mL^{-1}. Total bacterial ammonia oxidizer abundance was determined by competitive PCR amplification of 16S rRNA genes. Treatments were Tr 1, conventional tilling; Tr 2, no tilling; Tr 5, *Populus* perennial cover crop; Tr 7, historically tilled. Suffixes T and F indicate tillage and fertilization, respectively. Error bars represent the standard errors. (From Phillips, C.J., D. Harris, S.L. Dollhopf, K.L. Gross, J.I. Prosser, and E.A. Paul. 2000a. Effects of agronomic treatments on structure and function of ammonia-oxidizing communities. Appl. Environ. Microbiol. 66:5410–5418.)
FIGURE 27.8 Abundance and ratios of abundances (in boxes) of bacterial (AOB) and archaeal (AOA) ammonia oxidizers, estimated by qPCR amplification of *amoA* genes, in 12 soils with a range of soil management and fertilization histories. (From Leininger, S., T. Urich, M. Schloter, L. Schwark, J. Qi, G.W. Nicol, J.I. Prosser, S.C. Schuster, and C. Schleper. 2006. Archaea predominate among ammonia-oxidizing prokaryotes in soils. Nature 442:806–809.)

Quantification of archaeal and bacterial *amoA* genes provided the first evidence for a significant role for archaea in soil nitrification (Leininger et al., 2006). Archaeal *amoA* genes were more abundant in all soils investigated, sometimes by two orders of magnitude (Figure 27.8). qPCR has also been used to compare abundances of *amoA* gene transcripts, which may provide a better indication of relative activities of bacterial and archaea (see below), but gene and gene transcript abundances do not necessarily relate directly to soil activity (Prosser and Nicol, 2008).

27.3.3 Nitrifier Activity and Nitrification Rates

27.3.3.1 Growth and Activity of Laboratory Cultures

Growth parameters and cell activities have been measured for pure cultures of a limited number of ammonia and nitrite oxidizers in cell suspensions, batch culture, and continuous culture. Growth kinetics are typical of those of other bacteria. In batch culture, cell abundance increases exponentially until ammonium or nitrite is fully utilized or, for ammonia oxidizers, pH reduces specific growth rate. Product concentration exhibits quasi-exponential increases and can be used to determine specific growth rate in standard batch cultures. Maximum specific growth rates of cultivated strains fall within the range $0.02-0.09\,h^{-1}$ (Prosser, 1989). However, detailed studies of growth kinetics and parameters have been restricted to strains isolated on high concentrations of substrate and maintained in laboratory culture for extended periods, potentially selecting faster growing strains. Michaelis–Menten and Monod kinetics have been used to describe the influence of substrate or oxygen concentration on cell activity (in cell suspensions) or specific

growth rate (in chemostats), respectively. Saturation constants for growth and activity of bacterial ammonia oxidizers fall within the ranges $0.12-14\,mM\ NH_4^+/NO_2^-$, and $0.05-0.07\,mM$ NH_4^+/NO_2^-, respectively. Total cell counts enable calculation of cell activities and cultivated ammonia oxidizers have activities in the range $0.9-31.3\,fmol\ NO_2^-/NO_3^-\ cell^{-1}\ h^{-1}$ (Prosser, 1989).

27.3.3.2 Growth and Activity in Soil

In the soil, growth parameters will be influenced by a number of factors. Most soil nitrifiers are likely to be attached to surfaces, possibly in biofilms, and NH_4^+ will be adsorbed onto negatively charged minerals and organic matter. Although this can be utilized by ammonia oxidizers, specific growth rate is believed to be controlled by concentrations of ammonia in soil solution, rather than total (extractable) ammonium concentration. Ammonia oxidation rates of cultivated ammonia oxidizers are therefore reduced in soils with high cation exchange capacity due to reduction in soluble ammonia concentration and pH (Stark and Firestone, 1995; Hommes et al., 1998). Ammonia concentration will also vary throughout soil, due to heterogeneity and complexity in soil physicochemical characteristics and spatial and temporal variation in ammonia supply and utilization. These, in turn, contribute to heterogeneity in nitrifier diversity and community structure and kinetic analysis of ammonia oxidation in natural soil therefore averages activities of all members of the community occupying microenvironments with a range of conditions.

Kinetic constants can be determined in soil slurries (Stark and Firestone, 1996) or in systems that maintain some soil structure, in which moisture content can be controlled (Stark and Firestone, 1995). This approach often leads to constants that differ

significantly from those obtained in pure cultures. For example, Stark and Firestone (1996) reported a K_m value of $15\,\mu M\ NH_4^+$ for soil ammonia oxidation, significantly lower than those for laboratory cultures. The complexity of soil communities and the soil environment make it difficult to interpret these values, but they may be more relevant, possibly reflecting our inability to isolate truly representative strains. This may be particularly relevant when considering competition between ammonia oxidizers, plants, and soil heterotrophs for ammonium. Autotrophic ammonia oxidizers are often considered to be poor competitors, because of high saturation constants determined for pure cultures, but the low values observed by Stark and Firestone (1996) suggest much greater competitive ability at low ammonium concentration. Estimates of cell activities for soil nitrifiers traditionally relied on MPN counts but values are now being reassessed using molecular abundance measurements and often do not differ substantially from those obtained in pure cultures of soil ammonia oxidizers.

It is interesting to consider the relevance of these growth parameters for soil nitrifiers. High maximum specific growth rates will provide an advantage where ammonium concentration is high but, in many situations, ammonium concentration will be low and high substrate affinity will be advantageous (Taylor and Bottomley, 2006). However, the ability to respond rapidly to increases in ammonium concentration and survive starvation may be more important than growth parameters traditionally considered to give nitrifiers a competitive advantage.

Nitrate production in soil is often described in terms of logistic growth kinetics, assuming that all cells will experience similar conditions and have similar activities and growth rates. In fact, nitrate production curves can be described equally well by considering ammonia oxidizers as spatially separated clusters, growing on discrete sources of ammonium within microenvironments. Onset of activity in these microaggregates or microenvironments will be determined by the speed of recovery following appearance of ammonia. Cessation of activity will occur when acid production limits growth. Molina (1985) showed that nitrate production kinetics followed the cumulative distribution of these lag periods, suggesting that recovery from starvation may be more important than other growth parameters and that nitrification may be limited, locally, by acidification of microenvironments, rather than low concentrations of ammonia.

27.3.3.3 Nitrification Rates in Soil

Soil nitrification process rates are frequently measured without reference to the abundance or diversity of nitrifier communities present, effectively treating soil as a "black box." Potential nitrification is determined as the rate of nitrification under optimal conditions. It is calculated as the rate of ammonia consumption or nitrite + nitrate production during incubation, at constant temperature, of soil or soil slurry at nonlimiting ammonia concentration. Ammonia may be added if ammonia concentrations in soil are limiting and soils are aerated, usually by rapid shaking of soil slurries, to minimize loss of nitrate through denitrification. Potential nitrite oxidation can be determined by addition of nitrite, rather than ammonia.

In the absence of significant nitrifier growth, zero order kinetics are observed and nitrate production rates are the product of nitrifier specific activity and biomass or cell concentration. In fact, this method has been used to estimate nitrifier biomass. If nitrifier abundances are low and/or incubation is continued, growth will lead to accelerating rates of nitrate production, which can be used to estimate the maximum specific growth rate of soil nitrifiers. Similarly, if ammonia concentration is low in relation to saturation constants for ammonium, the rate of nitrate production will decrease during incubation, as ammonium is utilized.

A major complication in measuring soil nitrification is the effect of other nitrogen cycle processes on ammonia and nitrate concentrations. Mineralization will increase ammonia supply; denitrification, immobilization, and leaching will remove nitrate; and plant uptake can reduce ammonia and/or nitrate. These factors are considered in net nitrification rate, calculated as nitrate production minus nitrate consumption, and gross nitrification rate, calculated as nitrate production plus nitrate consumption. Net nitrification rate is measured in the same way as potential nitrification rate but without attempts to inhibit denitrification, by aeration, or other nitrate consumption processes. Where ammonia concentrations are low, sensitivity can be increased by use of stable isotope methods, which are also necessary for determination of nitrate consumption in measuring gross nitrification. One approach is to add $^{15}NH_4^+$ as a tracer and measure production of $^{15}NO_3^-$. This suffers from the need to add ammonium, potentially stimulating nitrification, dilution of $^{15}NH_4^+$ by ammonium from mineralization, and lack of assessment of heterotrophic nitrification (Hart et al., 1994). In a second approach, the pool dilution method, soil is amended with $^{15}NO_3^-$ and its dilution by unlabeled nitrate produced by nitrifiers from unlabeled ammonium is measured (Barraclough and Puri, 1995). When combined with specific inhibitors of ammonia oxidation, such as acetylene or nitrapyrin, these techniques can distinguish autotrophic and heterotrophic nitrification. More sophisticated stable isotope approaches are used for discrimination of nitrogen cycle processes. These include addition of double-labeled compounds ($^{14}NH_4^{15}NO_3$ or $^{15}NH_4^{15}NO_3$), measurement of variations in $^{15}N/^{14}N$ and $^{18}O/^{16}O$ isotope ratios, and analysis of isotopomers, which discriminate between labeling of nitrogen atoms within the N_2O molecule (Sutka et al., 2006; Ostrom et al., 2007).

Nitrification rates can be determined in laboratory microcosms or mesocosms, or in the field. Microcosms are useful for assessing the influence of environmental factors on nitrification under controlled and well-monitored conditions. Field measurements may be more relevant where effects of naturally changing environmental conditions are being studied, including the influence of plant communities. Rates measured in soil are more variable than in pure culture systems, due to heterogeneity in soil physicochemical conditions, in particular ammonium concentration, pH and oxygen concentration, and heterogeneity in nitrifier biomass and community composition. Variability is greatest in unmanaged grasslands soils, where ammonia

concentration is often determined by grazing patterns of sheep and cattle and concentration of ammonium in urine patches. There is evidence for reduced variability in nitrification rates within agricultural soils, through increased homogeneity of pH, ammonia concentration, and ammonia oxidizer communities (Webster et al., 2002). As a consequence, deviations from expected kinetics should not be ignored, as they may provide important information on the factors controlling nitrification.

27.3.4 Nitrifier Communities and Diversity

Nitrifier communities are now routinely characterized using molecular methods for analysis of 16S rRNA and *amoA* gene sequences amplified from nucleic acids extracted directly from soil. Specific primers are available for betaproteobacterial ammonia oxidizer 16S rRNA (Kowalchuk et al., 1997; Purkhold et al., 2000; Mahmood et al., 2006) and *amoA* genes (Rotthauwe et al., 1997; Stephen et al., 1999; Webster et al., 2002), for archaeal and crenarchaeal (not necessarily ammonia oxidizer) 16S rRNA genes, and for crenarchaeal *amoA* genes. Nitrite oxidizer communities may be investigated using primers for 16S rRNA and nitrite oxidoreductase genes, but separate primers sets are required for *Nitrobacter* and *Nitrospira* (Freitag et al., 2005; Wertz et al., 2008). No specific primers are available for heterotrophic nitrifiers.

Amplicons are analyzed by cloning and sequencing, to determine phylogenetic relationships within community members and to identify phylotypes present, by comparison with sequences in databases. More rapid, but less detailed analysis of communities is achieved using DNA fingerprinting methods, such as denaturing gradient gel electrophoresis (DGGE) (e.g., Nicol et al., 2008), temperature gradient gel electrophoresis (TGGE) (e.g., Gray et al., 2003), or terminal-restriction fragment length polymorphism (T-RFLP) (e.g., Horz et al., 2000; Bottomley et al., 2004) analysis. These allow analysis of changes in nitrifier communities associated with different environmental factors and soil management treatments and identification of phylotypes dominating communities and responding most to change.

Many studies target RNA, rather than DNA, enabling assessment of the activities of different phylotypes. DNA is removed from extracted nucleic acids, RNA is reverse transcribed to DNA and genes are then amplified, using either 16S rRNA or functional gene primers. rRNA-targeted analysis of 16S rRNA genes increases sensitivity, as cells contain more ribosomes than rRNA genes, and also assesses general cellular activity, on the assumption that actively growing cells will contain more ribosomes than dormant cells. Amplification of functional genes from mRNA assesses transcriptional activity. Both approaches allow quantification of active nitrifiers and identification of phylotypes that are active (e.g., Leininger et al., 2006; Nicol et al., 2008). Stable isotope probing has also been used to determine which nitrifiers are actively fixing carbon dioxide. This involves incubation of environmental samples in the presence of ^{13}C-labeled CO_2 and molecular analysis of ^{13}C-labeled and unlabeled nucleic acids,

after separation by density gradient centrifugation (Freitag et al., 2006; Jia and Conrad, 2009). ^{13}C-labeled DNA and RNA will only contain gene sequences of nitrifiers that have assimilated CO_2. Correlation with nitrification activity is strong evidence of which nitrifiers are active in the soil and indicated that bacteria, rather than archaea, may be responsible for nitrification in an agricultural soil (Jia and Conrad, 2009).

These techniques now enable meaningful studies of nitrifier communities in soil. Their major advantage is the avoidance of the requirement to cultivate these slow-growing organisms but sequence analysis also provides much easier and more reliable phylogenetic analysis and identification. Analysis of both 16S rRNA and *amoA* gene clone libraries from soil demonstrates high levels of diversity in bacterial ammonia oxidizers and duplicate sequences are rarely seen (Stephen et al., 1996; Prosser and Embley, 2002). Environmental sequences differ from those of pure cultures but are sometimes identical to those of ammonia oxidizers enriched from the same soil (Smith et al., 2001). Environmental sequences generally confirmed phylogenies based on cultivated ammonia oxidizers but indicate the existence of two groups not represented in cultivated ammonia oxidizers and the possible subdivision of *Nitrosospira* into five clusters (Table 27.3). Cultivation-based studies indicated that nitrosomonads were "typical" soil organisms but molecular studies demonstrated that most soils are dominated by nitrosospiras (Stephen et al., 1996; Prosser and Embley, 2002). This is believed to reflect selection of nitrosomonads in laboratory cultures and *Nitrosomonas* is frequently found in cultures in final dilutions of MPN counts, even in soils dominated by *Nitrosospira*.

Congruence of phylogenies of bacterial 16S rRNA and *amoA* genes (Purkhold et al., 2003) allows cross-referencing of analyses using both approaches, but this is more difficult for crenarchaeal ammonia oxidizers, because of the lack of soil isolates and enrichment cultures. Most soil crenarchaeal 16S rRNA genes fall within the 1.1b group, but a significant number are also found in the "marine" 1.1a and 1.1a-associated groups (Table 27.3). Crenarchaeal *amoA* sequences have been amplified from all soils investigated, show high diversity, and most fall within a single clade. Again, however, a small but significant number of *amoA* sequences fall within a group more commonly amplified from marine samples. Metagenomic studies show an association of *amoA* sequences with Group 1.1b and there appear to be links between clusters within these groups, based on distributions of sequences from soils of different pH (Nicol et al., 2008; Tourna et al., 2008).

Nitrite rarely accumulates in soil and attention has generally focused on ammonia oxidizer communities, which are seen as a more important control point in nitrification. In addition, study of nitrite oxidizers is made more difficult by the requirement for different primer sets for *Nitrobacter* and *Nitrospira*. Phylogenetic analysis of 16S rRNA gene sequences from soil indicates greater diversity within *Nitrospira* than *Nitrobacter* (Freitag et al., 2005), as in other environments (Daims et al., 2000; Maixner et al., 2006). Analysis of the nitrite oxidoreductase functional gene, *nxrA*, suggests some sequence diversity within *Nitrobacter* (Poly et al., 2008; Wertz et al., 2008) but has not yet been attempted with *Nitrospira*.

27.3.5 Links between Nitrifier Communities and Soil Nitrification Activity

Techniques for measurement of soil nitrification rates, and the influence of soil conditions on environmental change on rates, have been available for many years. The major advance in the past decade has been the ability to characterize nitrifier communities, and to determine the links between nitrification rates and nitrifier abundance, community structure, and diversity. These studies have involved analysis of nitrifiers in soils with different physico-chemical characteristics, changes in communities in response to changing conditions, and, more recently, analysis of in situ activity. The major factors investigated are those considered to be most important in controlling soil nitrification: pH and ammonium concentration. Most studies have focused on bacterial ammonia, rather than nitrite oxidizers, and, more recently, the potential role of archaeal ammonia oxidizers in soil nitrification.

27.3.5.1 Soil pH

Cultivated bacterial ammonia oxidizers do not grow in batch culture below pH 7, because of reduced availability of NH_3, due to ionization (Allison and Prosser, 1991; Jiang and Bakken, 1999a). This is also considered to be the major reason for low nitrification rates in acid soils, although a survey of gross nitrification rates in a wide range of soils indicates no significant effect of soil pH (Booth et al., 2005). Acidophilic heterotrophs may be responsible for nitrification in some acid soils, but autotrophic nitrification occurs in soils with pH values as low as 3 (De Boer and Kowalchuk, 2001). In addition, bacterial autotrophic ammonia oxidizers are readily enriched from acid soils and molecular data indicate the presence and abundance of both bacterial and archaeal *amoA* genes.

In agricultural systems, liming of acid soils increases nitrification rates and consequent loss of ammonium-based fertilizer and leaching of nitrate. Knowledge of soil pH is important in predicting rates of nitrification and optimizing the timing of application of fertilizer and nitrification inhibitors. In forest ecosystems, and other nonmanaged acid soils, nitrification rates are low. However, ammonia concentrations may be high and soils may be nitrogen-saturated when nitrogen supply exceeds plant demand. Such high concentrations may themselves be a result of low nitrification rates, because of low pH, or due to atmospheric nitrogen deposition. These soils may have significant nitrification potential if pH is increased, through liming or clear-cutting. Ammonia oxidizers are generally less abundant in acid soils (typically 10^3–10^4 cells g^{-1} soil) and sometimes below detection limits of both MPN and qPCR methods (Schmidt et al., 2007). However, increasing pH, by liming, can increase abundance to detectable levels (Backman et al., 2003) and may lead to high rates of nitrification and increased nitrous oxide production.

Characterization of bacterial ammonia oxidizers in soils from a range of geographical regions provides evidence for pH selection of different *Nitrosospira* phylotypes, with increased relative abundance of *Nitrosospira* cluster 2 sequence-types in acid soils and of *Nitrosospira* cluster 3 at higher pH (Kowalchuk and Stephen, 2001). Selection is more evident in pH gradients
FIGURE 27.9 The influence of soil pH on bacterial ammonia oxidizer community structure. The relative abundances of *Nitrosospira* clusters 2, 3, and 4 and *Nitrosomonas* cluster 6a estimated as the relative intensities of DGGE bands following amplification of ammonia oxidizer 16S rRNA genes from DNA extracted from soil maintained at a range of pH values. (From Stephen, J.R., G.A. Kowalchuk, M.A.V. Bruns, A.E. McCaig, C.J. Phillips, T.M. Embley, and J.I. Prosser. 1998. Analysis of beta-subgroup proteobacterial ammonia oxidizer populations in soil by denaturing gradient gel electrophoresis analysis and hierarchical phylogenetic probing. *Appl. Environ. Microbiol.* 64:2958–2965.)

maintained for many years. Analysis of one such site, with a gradient from pH 3.9–6.6, established for 36 years, showed a change in dominance from *Nitrosospira* cluster 2 to cluster 3 sequences as soil pH increased (Figure 27.9; Stephen et al., 1998). The stability of these long-term community effects was confirmed by analysis of the same soils 9 years later (Nicol et al., 2008). The latter study also found significant pH-associated differences in crenarchaeal *amoA* gene sequence types and determined relative abundances and transcriptional activities of bacterial and archaeal ammonia oxidizers (Figure 27.10). Crenarchaeal *amoA* genes and gene transcripts were always more abundant than bacterial genes, suggesting a greater contribution by crenarchaea to ammonia oxidation in these soils. The most striking effect of pH was, however, on the ratio between *amoA* genes and gene transcripts, which may be a better measure of activity than transcript number (Nicolaisen et al., 2008; Freitag and Prosser, 2009). With increasing soil pH, this ratio fell sharply for crenarchaeal genes, and increased for bacteria, and was greater for bacteria above pH 6.5. The links between *amoA* transcriptional activity and nitrification rate require further study, but the results indicate that the relative contributions of crenarchaea to nitrification may be greater in acid soils. The results were confirmed in short-term studies in which crenarchaeal and bacterial transcriptional activities were compared in microcosms containing mixtures of low and neutral pH soil readjusted to pH 4.5 and 7 (Nicol et al., 2008).

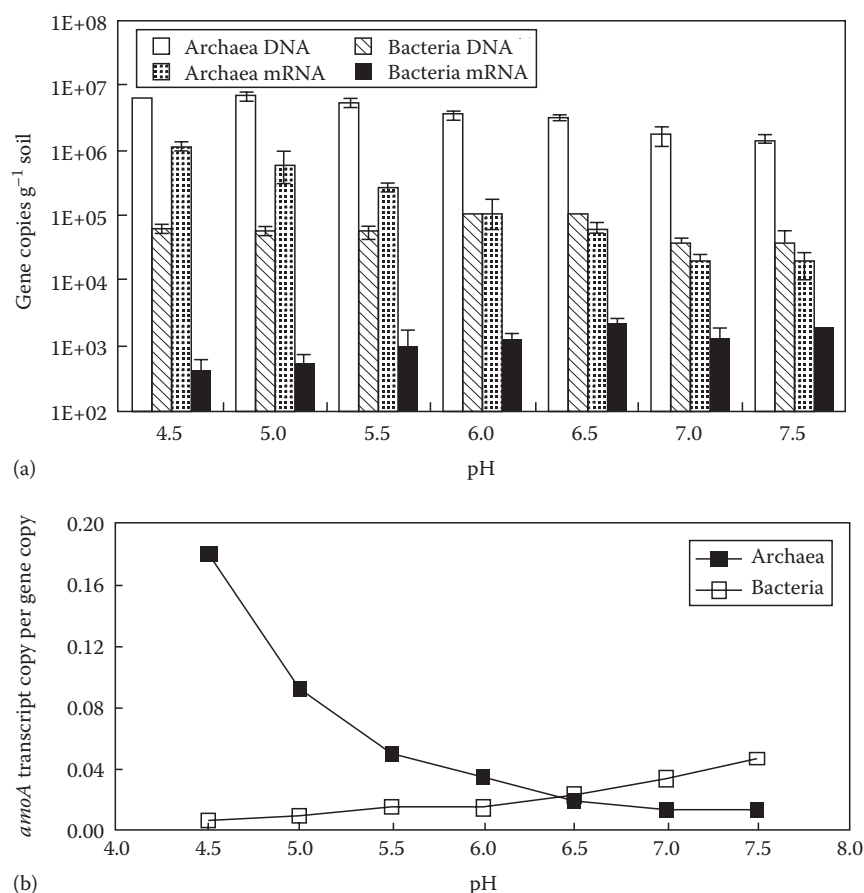
Growth and activity of ammonia oxidizers in low pH soils may result from protection by growth on anionic surfaces (where ammonium will be concentrated), protection in biofilms, activity in microenvironments in which pH is neutral, and


FIGURE 27.10 The influence of soil pH on bacterial and crenarchaeal ammonia oxidizer abundance and transcriptional activity. Abundances were determined by qPCR amplification of *amoA* genes and *amoA* gene transcripts in DNA extracted from soil maintained at a range of pH values. (a) Crenarchaeal and bacterial *amoA* gene and transcript abundance. (b) Ratios of crenarchaeal and bacterial gene transcript:gene abundance. Error bars represent standard errors of replicate field samples at each soil pH. (Based on data in Nicol, G.W., S. Leininger, C. Schleper, and J.I. Prosser. 2008. The influence of soil pH on the diversity, abundance and transcriptional activity of ammonia oxidizing archaea and bacteria. Environ. Microbiol. 10:2966–2978.)

favorable for growth, or utilization of urea as an ammonium source (De Boer and Kowalchuk, 2001). Ammonium oxidizers with urease activity convert ammonia generated intracellularly, after uptake of urea, and growth on urea is independent of pH in the range 4–8 (Burton and Prosser, 2001). Physiological studies are required to determine whether these characteristics are responsible for selection of different phylotypes in acid soils.

27.3.5.2 Nitrogen Fertilization and Ammonia Concentration

The nitrification potential of a soil will be determined by nitrifier biomass, specific rates of ammonia oxidation, and soil physicochemical conditions, particularly pH and oxygen concentration. If conditions are favorable for nitrification, nitrifier biomass will be determined by the balance between flux of ammonia into the soil and death and removal. Flux, in turn, will be controlled by rates of addition, through mineralization, input of animal waste, fertilizer addition and atmospheric deposition, and removal, through root uptake and conversion to nitrate. In contrast, specific rates of nitrification will vary with ammonia concentration. Quantitative effects of ammonia

concentration on specific growth rate vary between ammonia oxidizer phylotypes, through differences in maximum specific growth rates, substrate affinities and sensitivity to high ammonia concentration. Growth rate will be determined by the concentration of ammonia in the soil solution, rather than bulk ammonia concentrations, because of adsorption to negatively charged soil particles. Measured nitrification rates will also be influenced by heterogeneity in ammonium concentrations, with high and potentially inhibitory concentrations of ammonia near decomposing organic matter, fertilizer particles, or urine patches. Heterogeneity will be reduced by plowing and there is evidence for reduced variability in nitrification rates (White et al., 1987), physicochemical characteristics, and ammonia oxidizer diversity in soils that are not plowed (Webster et al., 2002; Patra et al., 2006; Dell et al., 2008).

Ammonia oxidizer abundance is generally greater in fertilized soils and those subjected to disturbance by fertilizer application and plowing (Figure 27.8) (Bruns et al., 1999; Phillips et al., 2000a, 2000b). Bacterial ammonia communities are influenced by agricultural and land management practices (reviewed in Kowalchuk and Stephen, 2001), with evidence for selection of *Nitrosospira*

cluster 3 in fertilized and managed systems, *Nitrosospira* cluster 4 dominant in unmanaged systems and *Nitrosomonas*-like sequences in heavily fertilized grassland soils (Webster et al., 2002) and compost (Kowalchuk et al., 1999; Avrahami et al., 2002). Ammonia concentration also affects development of communities in soil microcosms (Mahmood and Prosser, 2006), with increases in *Nitrosospira* cluster 2 phylotypes at all applied nitrogen levels and in clusters 3 and 4 at low and high nitrogen, respectively. Nitrite oxidizers also respond to long-term ammonia fertilizer application and plowing (Freitag et al., 2005), with changes in *Nitrosospira* but not *Nitrobacter* communities.

Lack of information on comparative physiology of nitrifiers makes it difficult to explain community changes or their significance for ecosystem function. However, some changes may be due to inhibition by high ammonia concentration, which will occur in urine patches following urea hydrolysis. Webster et al. (2005) found that nitrification of artificial urine added to unmanaged soil microcosms occurred only after lag periods of several weeks in samples dominated by *Nitrosospira* cluster 3a strains, which are sensitive to high ammonia concentration. Microcosms dominated by ammonia-tolerant *Nitrosospira* cluster 3b strains showed only short lag periods. Bacterial ammonia oxidizer community structure consequently impacted significantly on the availability of ammonia for plant growth. These effects of grazing were diminished by long-term application of inorganic nitrogen fertilizer, which will have reduced heterogeneity and also increased abundance of all ammonia oxidizer phylotypes, such that lag phases were independent of urine addition. Differences in nitrification rate and ammonia oxidizer community structure and abundance have also been reported in grazed and ungrazed field sites (Le Roux et al., 2003, 2008; Patra et al., 2005). Communities and nitrification rates reverted after switches from grazed to ungrazed, and vice versa, within several months, returning to values seen in equivalent, unaltered soils within 12 months.

27.3.6 Control and Management of Soil Nitrification

Conversion of ammonia-based fertilizers to nitrate, and subsequent loss and environmental pollution through leaching and denitrification to nitrous oxide, has led to development of commercial application of nitrification inhibitors. Inhibitors also have an important role in distinguishing different nitrogen cycling processes, when measuring nitrification rates in soil and in investigations of nitrifier biochemistry and physiology (Arp and Stein, 2003).

Commercial inhibitors target ammonia oxidation; and Subbarao et al. (2006) and Singh and Verma (2007) review current literature on available compounds, their mechanisms of action, their effectiveness in controlling soil nitrification in agricultural soils, and factors determining choice of inhibitor. Most research has been carried out on Nitrapyrin [2-chloro-6-(trichloromethyl) pyridine, *N*-Serve] but other commonly used inhibitors include dicyandiamide (DCD), allylthiourea,

3,4-dimethylpyrazol-phosphate (DMPP), 2-amino-4-chloro-6-methylpyrimidine (AM), and acetylene. Nitrite oxidation is inhibited by chlorate and has been used to measure soil nitrification as nitrite production, avoiding the need for analysis of both nitrite and nitrate. Traditionally, nitrification inhibitors have been used to reduce fertilizer loss, through leaching and denitrification of nitrate, and associated nitrate pollution. More recently, their value has been reassessed in relation to reducing greenhouse gas production by both nitrifiers and denitrifiers. The value of agricultural use of nitrification inhibitors has been reviewed for a number of studies (Wolt, 2004), and include average 7% increases in crop yield and 51% decreases in nitrous oxide emissions.

Despite conflicting reports, reviewed by Subbarao et al. (2006), there is evidence that allelopathic inhibitors of nitrification are produced, naturally, by plant and tree roots. Inhibitory compounds include phenolics, terpenes, and flavonoids and may function to sustain levels of soil ammonium, particularly in climax ecosystems. Mechanistic studies of allelopathic inhibition are hampered by technical difficulties in determining the amounts and inhibitory activities of complex organic compounds in soil. Recently, a luminescence-marked strain of *Nitrosomonas europaea* was used to screen for ammonia oxidizer inhibitors produced by a range of plants (Subbarao et al., 2007), and this approach may increase our understanding of plant-derived inhibitors and more efficient and sustainable measures to reduce fertilizer loss.

Both ammonia and nitrite oxidizers are protected from the effects of inhibitors by attachment to surfaces, including soil minerals and organic matter, and approximately 10-fold higher concentrations are required for inhibition in soil. Despite the availability of molecular techniques for analysis of nitrifier community structure, there is little information on variations in sensitivity of different ammonia oxidizer phylotypes. Wrage et al. (2004b) found that acetylene inhibited nitrous oxide production by *Nitrosomonas europaea* but not *Nitrosospira briensis*, despite inhibition of ammonia oxidation by both strains. Variation in sensitivity of different ammonia oxidizers, and differences in sensitivity of bacterial and archaeal ammonia oxidizers, may have implications for the effectiveness of nitrification inhibitors and environmental consequences.

27.3.7 Conclusions

Nitrification is central to the soil nitrogen cycle and results in considerable economic losses of nitrogen fertilizer and environmental pollution, through increased levels of atmospheric nitrous oxide and groundwater nitrate. The past decade has seen major advances in our knowledge of the diversity and community structure of soil nitrifiers. This complements existing, extensive knowledge on soil nitrification processes, which has also been advanced, in particular, through developments in use of ^{15}N-based techniques for unraveling different nitrogen cycling processes. Ammonia- and nitrite-oxidizing bacteria are considerably more diverse than indicated by cultivation studies alone;

and crenarchaea, in addition to bacteria, can oxidize ammonia and are abundant in soil. Molecular techniques for analysis of microbial communities continue to advance rapidly and are likely to increase our understanding of the links between nitrifier community structure, rates of soil nitrification, and the impact of environmental change. Integration of process and community studies has the potential to increase our ability to control nitrification, to reduce fertilizer demand, and to reduce greenhouse gas production.

27.4 Denitrification

Jean-Claude Germon

Laurent Philippot

27.4.1 Introduction

The considerable increase in nitrogen fertilization in the second half of the twentieth century and the damage caused by the acceleration of the nitrogen cycle in the disturbed environment raised interest in the fate of nitrogen in soils, in particular gaseous losses and denitrification (Galloway et al., 2008). Denitrification, which was first described by Gayon and Dupetit (1882), is a microbial respiratory process consisting in the sequential reduction of nitrate (NO_3^-) or nitrite (NO_2^-) to nitric oxide (NO), nitrous oxide (N_2O), or nitrogen gas (N_2). These nitrogen oxides are used as alternative electron acceptors

when oxygen for generating a transmembrane proton electrochemical potential across the cytoplasmic membrane is limited. As a consequence, denitrification occurs in soils when nitrate or nitrite is available as a substrate and when there is little or no oxygen. Denitrification also tends to concentrate around hot spots of organic matter (Parkin, 1987), since the most common energy sources for denitrifying bacteria are organic compounds. Denitrification exhibits both a high temporal variability, generally associated with rain events, and a high spatial variability with variations by orders of magnitude even within small areas (Folorunso and Rolston, 1984).

Denitrification is of interest for several reasons. Firstly, from an agronomical point of view, denitrification is responsible for the loss of an essential plant nutrient as the reduction of NO_3^- to gaseous nitrogen depletes the soil of NO_3^-. It has been reported that between 0% and 25% of the applied nitrogen can end up as nitrogen gas or N_2O, thus limiting crop production (Aulakh et al., 1992; DeKlein and van Logtestijn, 1994; Mogge et al., 1999). From an environmental point of view, denitrification contributes to global warming by emitting N_2O, which is one of the major greenhouse gases. Nitrous oxide has a global warming potential 300 times higher than that of CO_2 as estimated by the Intergovernmental Panel on Climate Change (IPCC) and contributes up to 6% of the anthropogenic greenhouse effect (Cicerone, 1989). Both N_2O and NO are also involved in the destruction of the earth's ozone layer (Waibel et al., 1999). From a human health point of view, denitrification is of interest as it removes NO_3^- from water. There is a potential health problem primarily for young children if the nitrate concentration rises above the levels acceptable for drinking water quality (World Health Organization standard of $10\,mg\,L^{-1}\,NO_3^-$–N). The reduction of NO_3^- to NO_2^- by bacteria in the digestive tract can lead to a disorder called methemoglobinemia, as, after entering the blood stream, NO_2^- reacts with hemoglobin, reducing the oxygen-carrying capacity and causing the asphyxiation of new born babies (Shearer et al., 1972). The ingestion of high levels of NO_3^- may also result in the formation of carcinogenic nitrosamines by the reaction of ingested secondary aliphatic and aromatic amines with NO_2^- in the human stomach.

Despite these effects of denitrification on agriculture and the environment, which are vital for human welfare, many aspects of this process are still poorly understood. There is a lack of interdisciplinary collaboration between scientists, which is an obstacle to providing a comprehensive understanding of denitrification. Significant progress could be achieved through an integrative approach linking field measurements of denitrification N flows to the genetics, biochemistry, physiology, and ecology of the denitrifiers.

27.4.2 Denitrification Pathway

The complete denitrification process consists of a sequential process of nitrate respiration, nitrite respiration, nitric oxide reduction, and nitrous oxide respiration (Figure 27.11). The first step is the reduction of nitrate to nitrite, which is catalyzed by
FIGURE 27.11 The four steps of the denitrification pathway.

the membrane-bound nitrate reductase (Nar) or the periplasmic nitrate reductase (Nap). The two types of nitrate reductases can be present in the same strain of bacteria (Carter et al., 1995; Roussel-Delif et al., 2005). The second step of the denitrifying pathway is a key step since it consists in the reduction of soluble nitrite to gaseous nitric oxide. This reaction distinguishes denitrification from the dissimilatory reduction of nitrate to ammonium and can be catalyzed either by a copper nitrite reductase (NirK) or a cytochrome cd_1 nitrite reductase (NirS) (Zumft, 1997). Although the structure and prosthetic metal of these enzymes are different, transfer of the gene encoding copper nitrite reductase to a mutant of *Pseudomonas stutzeri* lacking cytochrome cd_1 nitrite reductase due to a transposon Tn5 insertion in its structural gene can restore the denitrification pathway lost in the mutation (Glockner et al., 1993). All known denitrifiers possess only one of these two types of nitrite reductase. The next step, reduction of the toxic intermediate nitric oxide into nitrous oxide, is also performed by two types of enzyme: cNor or qNor. The first type of nitric oxide reductase (cNor) receives the electrons from cytochrome *c* or pseudoazurin and the second (qNor) receives the electrons from a quinol pool. The last step of the denitrification pathway, the reduction of the greenhouse gas nitrous oxide to dinitrogen, is catalyzed by the multicopper homodimeric nitrous oxide reductase (Nos) (Zumft, 1997).

The denitrification pathway is best described as the modular organization of the different steps. Denitrifiers may have a truncated denitrification pathway as was revealed by the complete genome sequencing of *Agrobacterium tumefaciens* C58, which lacks the *nosZ* gene encoding the catalytic subunit of the nitrous oxide reductase and is, therefore, genetically unable to reduce nitrous oxide. In addition, a few microorganisms cannot reduce nitrate and use nitrite as the first electron acceptor in the denitrification process. The distribution of the various denitrification reductases also varies between denitrifiers (Philippot, 2002). For example, the first two steps of the denitrification pathway are catalyzed by Nap and NirK in many denitrifying rhizobia while it is catalyzed by both Nar and Nap and NirS in *P. aeruginosa* strains.

In most studies, the expression of the denitrification reductases could be induced by a low O_2 partial pressure and presence of nitrogen oxides. In pure cultures, synthesis of the denitrification reductases after a shift to conditions favorable to denitrification can be achieved within a few hours (Baumann et al., 1996). Other factors such as soil pH can affect the expression or the activity of these enzymes. Environmental conditions can also have different effects on the reductases catalyzing the various

steps of the denitrification pathway, resulting in the accumulation of intermediates (Firestone et al., 1980; Thomsen et al., 1994). This is highly significant for the environment as it can result in changes in the N_2/N_2O ratio with increased emission of the greenhouse gas N_2O (see Section 27.4.5).

27.4.3 Denitrifying Organisms

27.4.3.1 Abundance and Diversity of Denitrifiers

When studying the respiratory capacities of bacteria isolated from various environments, many strains have been wrongly identified as denitrifiers. Mahne and Tiedje (1995), therefore, proposed two main criteria for identifying "true" denitrifiers: (1) nitrous oxide and/or nitrogen gas must be the main end product of nitrate or nitrite reduction and (2) this reduction must be coupled with a greater increase in growth than would occur if the nitrate or nitrite were simply acting as electron sinks. These criteria can be used to distinguish denitrifiers from bacteria reducing nitrate into ammonium (Cole, 1996) and bacteria able to reduce nitric oxide as a protection against nitrosative stress (Philippot, 2005).

Many soil prokaryotes can denitrify and the proportion of denitrifiers within the soil microbial community was estimated, using both culture based and direct molecular approaches, to be up to a few percents, giving a range of 10^5–10^8 denitrifiers per gram of soil (Tiedje, 1988; Vinther et al., 1999; Henry et al., 2004, 2006; Dandie et al., 2008; Hallin et al., 2009). The diversity of microorganisms able to denitrify is also very large, with more than 60 bacterial genera containing denitrifying strains as well as some archaea and fungi (Philippot et al., 2007). In one of the first comprehensive studies exploring denitrifying communities in soil, Gamble et al. (1977) found that the dominant isolated denitrifiers belonged to the *Pseudomonas* and *Alcaligenes* groups. In addition to these genera, other cultivation-based studies showed that the genera *Achromobacter*, *Ralstonia*, *Burkholderia*, *Bacillus*, and *Streptomyces* were numerically significant denitrifiers in soils (Garcia, 1977; Weier and Mac Rae, 1992; Chèneby et al., 2000, 2004; Dandie et al., 2007). Furthermore, the number of taxa known to include denitrifiers is likely continuing to increase as yet unknown soil microorganisms may also contribute to the overall denitrification process. As a consequence of this wide taxonomical diversity of denitrifiers, the distribution of the denitrification trait among microorganisms cannot be predicted using their taxonomical affiliation. While distantly related microorganisms can denitrify, closely related strains can exhibit very different respiratory pathways. For example, analysis of the ability to use nitrate as alternative electron acceptor among a collection of fluorescent pseudomonads showed that strains were denitrifiers, nitrate reducers, or neither (Clays-Josserand et al., 1995). Denitrifiers can also be involved in the other steps of the nitrogen cycle, such as nitrification or nitrogen fixation. For example, ammonia-oxidizing *Nitrosospira* and *Nitrosomonas* strains and several nitrogen-fixing rhizobia have been shown to be denitrifiers (Daniel et al., 1982; Bock et al., 1995; Shaw et al., 2006).

27.4.3.2 Ecology of Denitrifiers

There were very few studies of the ecology of denitrifiers in soil and other functional communities until the end of the 1990s owing to the lack of appropriate tools for targeting them in this complex environment. Molecular tools are now being developed or refined to assess both diversity and size of the denitrifying community in soil and other ecosystems (Taroncher-Oldenburg et al., 2003; Throbäck et al., 2004; Henry et al., 2006). The most common way of analyzing the soil denitrifier community is to extract the DNA from the soil and amplify it by PCR (Hallin et al., 2007). Since the ability to denitrify is not associated with any specific taxonomic group (Section 27.4.3.1), existing primers for studying denitrifiers target the genes encoding the various denitrification reductases, which are used as molecular markers for this community. Several techniques are available for analyzing the sequence polymorphism of PCR-amplified denitrification genes. The most informative technique is to clone and sequence the PCR amplicons, but a more rapid analysis is achieved using fingerprinting techniques (denaturing gradient gel electrophoresis [DGGE], terminal restriction fragment length polymorphism [T-RFLP], etc.). The polymorphism of the denitrification genes is used as a proxy for the level of diversity and composition of the denitrifier community. The size of the denitrifier community is now usually evaluated as the gene copy numbers per gram of soil using real-time quantitative PCR of the denitrification genes (Philippot and Hallin, 2005). Since the number of the denitrification gene copies per genome is between 1 and 3 but usually only 1, the gene copy numbers can be then converted into cell numbers. However, the major limitation of these methods is that they target all bacteria capable of denitrification and therefore do not distinguish those that are actively denitrifying at the time of sampling from the nondenitrifying fraction of the denitrifier community. The fact that these methods target potential denitrifiers is also a major drawback for the understanding of the relationships between the diversity and activity of the denitrifying community. Over the last 15 years, these molecular methods have mainly been applied to study how the denitrifying community in soil is affected by agricultural practices or environmental conditions, or more generally, to identify the factors controlling the size and the composition of this functional community.

The composition of the denitrifier community varied significantly between soil habitats (Cavigelli and Robertson, 2001; Priemé et al., 2002; Rich et al., 2003; Rich and Myrold, 2004). For agricultural soils, the main focus has been on the effect of fertilization on denitrifiers. It has been shown that the composition of the denitrifier community may be modified after a few weeks by high ammonium concentrations varying from 60 to 400 mg NH_4^+–N g^{-1} of dry soil (Avrahami et al., 2002). Organic fertilization can also modify the denitrifier community composition depending not only on the fertilization regime but also on the duration for which it is applied (Wolsing and Prieme, 2004; Dambreville et al., 2006; Schauss, 2006). In a long-term study on the impact of the fertilization regime on denitrifiers in an experimental field amended with calcium nitrate, ammonium sulfate, cattle manure, and sewage sludge, fingerprint analyses showed the highest differences in the denitrifier community structure in plots treated with ammonium sulfate and sewage sludge, which exhibited the lowest pH (Enwall et al., 2005). When analyzing the size of the denitrifier community by quantitative PCR, the numbers of denitrification genes encoding the nitrite and nitrous oxide reductases were one to two orders of magnitude lower in the ammonium sulfate treatment compared with the other treatments, thus confirming the strong impact of soil pH on this functional community (Hallin et al., 2009).

The presence of plants can also influence the denitrifying community since the availability of all the major factors regulating denitrification—organic compounds, oxygen and nitrate—are directly and indirectly modified by the plant rhizosphere. Changes in the composition of the denitrifier community in the plant rhizosphere compared to the bulk soil have been reported in several studies (Chèneby et al., 2004). Plant species can also influence the composition of the denitrifier community in soil (Sharma et al., 2005; Bremer et al., 2007), probably through specific rhizodeposition (Mounier et al., 2004; Henry et al., 2008).

Recent studies showed that, similar to denitrification activity, the size and composition of the denitrifier community had a high spatial variability at the field scale with macroscale spatial dependence (several meters) (Philippot et al., 2009; Enwall et al., 2010). Characterization of denitrifier distribution patterns at field scale is an important step in modeling distribution of functional bacterial communities at a scale compatible with land management strategies and can help in the future bridge the gap between studies analyzing denitrification N flows and denitrifier community ecology.

27.4.4 Denitrification Activity in Soils

27.4.4.1 Methods of Measuring Denitrification Activity in Soil

Denitrification in soil was first measured by Dehérain and Maquenne (1882) who observed that nitrate reduction producing an N_2O and N_2 mixture occurred when the soil was enriched with organic matter and incubated in an oxygen-free atmosphere. Dehérain (1897) noted that this mechanism constitutes a nitrogen loss for growing plants but that its quantitative evaluation in soils is hindered by three main problems: (1) the simultaneous formation and reduction of nitrates, (2) the nitrogen gas produced is naturally diluted in the atmospheric nitrogen, and (3) the level of nitrogen loss is generally of the same order as the uncertainty of the total nitrogen measurements in soils. Denitrification is, therefore, still considered as a difficult process to measure (Groffman et al., 2006) and requires different methodological approaches for an accurate evaluation of the rates at different scales.

The first quantitative denitrification estimates in soil were performed using various nitrogen budgets and balances. Allison (1955) reviewed the N balances from several long-term lysimeter

field experiments and concluded that gaseous nitrogen losses from normal, well-aerated soils are not negligible and can represent 20% of the available mineral nitrogen during the year in cultivated, fertilized soils and 12% in uncultivated soils. From the previous synthesis, Broadbent and Clark (1965) drew the conclusion that it is difficult to reduce nitrogen losses by denitrification in cultivated fields to less than 15% of the mineral nitrogen available during the cultivation cycle. The main advantage of the N balance methodology is that it can be applied over a large range of scales, from plots to basins (Billen and Garnier, 1999), regions, countries (David et al., 2001), and open marine systems. This approach can be applied to evaluating the global N cycle to estimate the denitrification rate required to balance the cycle (Galloway et al., 2004). However, such balancing must take account of the various, major uncertainties in estimating the various N sources and sinks and changes in N storage pools (Kroeze et al., 2003). Nitrogen losses by denitrification estimated using mass balances must, therefore, be verified by direct measurements (Groffman et al., 2006).

Different nitrogen compartments can be distinguished using ^{15}N-labeled compounds. This improves the N balance sensitivity and makes it possible to measure denitrification directly in laboratory conditions by accumulation of labeled ^{15}N gaseous products (Wijler and Delwiche, 1954; Nömmik, 1956; Guiraud and Berliet, 1970). This methodology requires the added labeled nitrate to be homogeneously and rapidly mixed with the endogenous nitrate in the soil and an exact knowledge of the $^{15}N/^{14}N$ ratio in the denitrified nitrate to assay denitrified N using ^{15}N-labeled gases. Hauck et al. (1958) demonstrated that the ratio of the enriched species $^{15}N^{15}N$ and $^{14}N^{15}N$ can be used to estimate the $^{15}N/^{14}N$ ratio in the denitrified source. More direct measurements of the isotope mixing ratio can be obtained by an accurate isotope analysis of N_2O produced as an intermediate denitrification product (Stevens and Laughlin, 2001). In situ ^{15}N-labeled fertilization was used in many field experiments to estimate the N balance deficit at the end of the vegetation cycle, based on inorganic and organic nitrogen measurements. This was preferentially assigned to denitrification rather than to other gaseous loss mechanisms (Broadbent and Carlson, 1978; Dowdell and Webster, 1984; Recous et al., 1988; Addiscott and Powlson, 1992). However, this method is affected by measurement uncertainties on the different N pools analyzed (Myrold, 1991) and by the possible N losses by emission mechanisms other than denitrification. In situ denitrification can also be estimated by the aid of highly ^{15}N-labeled fertilizer applications and labeled gas emission measurements: This method requires high-performance mass spectrometry to measure the various diluted isotopic compounds produced and is not very sensitive: It was, however, sufficiently reliable to be considered as a standard way of comparing different methods (Mosier et al., 1986; Aulack et al., 1991). ^{15}N isotopes ($^{15}NO_3^-$ and $^{15}NH_4^+$) can be used as tracers to evaluate the contribution of nitrification and denitrification in soils to gaseous nitrogen oxide emission (Stevens et al., 1997; Russow et al., 2000; Wolf and Russow, 2000).

Mathieu et al. (2006) observed that, under unsaturated and saturated conditions, both processes were significantly involved in N_2O production, with 60% of $N–N_2O$ coming from nitrification under unsaturated conditions and 85%–90% of $N–N_2O$ coming from denitrification under saturated conditions. The proportion of nitrified N emitted as N_2O changed from 0.13% to 2.32% in unsaturated and saturated conditions, respectively.

The natural isotopic abundance variations can be used as an indicator of denitrification by assessing nitrogen isotopic fractionation and enrichment factors during this N transformation (Mariotti et al., 1982; Shearer and Kohl, 1988): They can allow estimating denitrification intensity in soils and aquifers such as basins, riparian, or benthic zones and rivers (Lehmann et al., 2003; Sebilo et al., 2003, 2006). However, isotopic fractionation can be affected by other N transformations such as nitrification or by diffusional constraints conditioning NO_3^- availability. Consequently, the magnitude of the isotope effect in a physically heterogeneous medium such as soil may not reflect the amount of NO_3^- reduced (Groffman et al., 2006).

The discovery of the inhibiting properties of acetylene (C_2H_2) on N_2O reduction by denitrifying bacteria (Federova et al., 1973; Balderston et al., 1976; Yoshinari and Knowles, 1976) paved the way for a significant development of techniques for direct measurement of soil denitrification in situ (Ryden et al., 1979a, 1979b; Mosier et al., 1986; Aulack et al., 1991) or in laboratory conditions (Klemedtsson et al., 1977; Yoshinari et al., 1977; Smith et al., 1978). Various acetylene-based methods have been used to measure in situ denitrification in agriculture or forest soils. The first was based on the use of in situ chambers and acetylene diffusion in soil (Ryden et al., 1979b; Rolston et al., 1982; Colbourn et al., 1984). This method was time-consuming, and it was difficult to ensure that the acetylene was distributed evenly throughout the pores in the soil. It has therefore been little used. The majority of measurements of denitrification in field conditions using acetylene inhibition are based on the use of undisturbed soil cores sampled in the field and incubated in laboratory conditions as close as possible to field conditions. Using either recirculating or static soil cores, this method provides a better control of acetylene distribution and other parameters regulating the denitrifying activity (Parkin et al., 1984; Ryden and Skinner, 1987; Hénault and Germon, 2000; Ullah et al., 2005; Van der Salm et al., 2007).

This method, however, suffers from several problems making its use controversial in various situations. The most important are (1) The inhibitory effect of C_2H_2 on ammonia oxidation by autotrophic microflora (Hynes and Knowles, 1978), which can decrease NH_4^+ conversion to NO_3^- and limit the denitrification rate in soils with a low nitrate content (Mosier, 1980); (2) possible microflora adaptation in some soils, biodegrading C_2H_2 after several days in a C_2H_2-enriched atmosphere leading to increased soil respiration and denitrification (Germon, 1980; Terry and Duxburry, 1985; Topp and Germon, 1986); and (3) an overestimated denitrification rate due to the lower electron flow required to reduce nitrate to N_2O rather than to N_2 (Myrold, 1991).

However, a comparison of N loss data obtained by C_2H_2 methods and by isotopic tracers indicated similar results with differences generally within the measurement variability (Parkin et al., 1985a; Myrold, 1991). In the absence of a viable alternative method and despite these limitations (Groffman et al., 2006), this approach continues to be a standard tool for evaluating denitrification in many situations (Ullah et al., 2005; Van der Salm et al., 2007; Woodward et al., 2009).

27.4.4.2 Regulation of Denitrification Activity in Soil

The denitrification rate in soil results from the activity of the denitrifying community, which is regulated by various environmental factors. Most works have indicated that the denitrifying activity is generally not limited by the lack of denitrifiers (see Section 27.4.3.1). This functional community is generally abundant in the upper soil horizons (Gamble et al., 1977; Chéneby et al., 1998; Hallin et al., 2009) and is significant in deeper horizons (Weier and Mac Rae, 1992), allowing denitrification in subsoils and aquifers (Mariotti, 1994; Hashimoto et al., 2005). In field conditions, denitrification rates exhibit considerable spatial and temporal variability (Folorunso and Rolston, 1984), which is the consequence of simultaneous regulation by a range of environmental factors, so that the activity has hot spots and hot moments. This variability must be taken into account in denitrification estimates, particularly in denitrification models (Groffman et al., 2009). Groffman et al. (1987) and Tiedje (1988) designed a conceptual schema with hierarchical control by environmental parameters, distinguishing between proximal controls (carbon, nitrate, oxygen) and distal controls (humidity, temperature, soil respiration, plants, etc.).

The first condition for denitrifying activity in soils is the presence of nitrogen oxidized forms, mainly nitrate or nitrite. The nitrate availability for denitrifiers depends on the rate of nitrate production and nitrogen fertilizer application, nitrate transport from solution in the soil to denitrifying microsites, and the rate of nitrate consumption by plants or microbes. The denitrification rate appears to be seriously limited by nitrate availability in unfertilized or slightly fertilized soils. However, in the majority of fertilized agricultural soils, denitrification is not or only slightly limited by nitrate availability (Barton et al., 1999). The regulatory effect of nitrate concentration on denitrification rate can be described by Michaelis–Menten kinetics with an apparent K_m dependent on the soil properties and generally of several orders of magnitude higher than the K_m measured on microorganisms. While a theoretical K_m in soil could be estimated from microbial cultures on a possible range of 0.01–0.1 mg N kg^{-1} dry soil (Myrold and Tiedje, 1985), K_m values higher than 20 mg N kg^{-1} dry soil have been observed in undisturbed soil cores (Hénault and Germon, 2000; Heinen, 2006a; Van der Salm et al., 2007).

Oxygen availability is generally considered to be the most important parameter regulating denitrification as oxygen inhibits the activity and neosynthesis of most denitrifying enzymes. Denitrification activity in apparently well-aerated soils is the consequence of the soil structure heterogeneity and the variable transfer of oxygen through the soil pores. Parkin and Tiedje (1984) observed a dramatic decrease in the denitrification rate in soil when the O_2 content in macropores is higher than 0.5%, while Sexstone et al. (1985) described a steep O_2 gradient in soil aggregates incubated in air and demonstrated that anaerobic centers were present in all aggregates that showed denitrification while not all aggregates that had anaerobic zones showed denitrification. The effect of aeration and oxygen transfer on soil denitrification has been described by various authors (Smith, 1980; Arah, 1990; Sierra et al., 1995). However, aeration in soil is strongly dependent on water content and, in particular, on water-filled pore space (WFPS). Linn and Doran (1984) described soil respiration, nitrification, and denitrification in relation to WFPS while Grundman and Rolston (1987) defined an exponential relationship between field denitrification rates and WFPS. This type of relationship has been confirmed by many authors and has been used in several models of soil denitrification (Johnsson et al., 1991; Hénault and Germon, 2000; Heinen, 2006a).

Denitrifiers are mainly heterotrophic organisms and the organic matter content was the first factor identified as limiting denitrifying activity in soils (Dehérain and Maquenne, 1882; Bremner and Shaw, 1958). Available organic carbon increases heterotrophic respiration in aerobic soils, decreasing soil oxygen concentrations and creating anaerobic microsites for denitrifiers. Significant relationships were reported between denitrifying activity and various forms of available carbon (Burford and Bremner, 1975; Standford et al., 1975; Reddy et al., 1982). Among the denitrification regulating factors, organic matter content is still considered to be the main control, suggesting that it may be possible to estimate the potential denitrifying activity directly from the soil carbon content or from the kinetics of carbon biodegradation (Hénault and Germon, 2000; Heinen, 2006a).

The pH is frequently reported as being another factor affecting denitrifying activity (Parkin et al., 1985b; Simek and Hopkins, 1999). Soil denitrifying activity is greatest at neutral pH and is significantly reduced at a pH lower than 5 or higher than 8.5. A limiting function of the pH on the denitrifying activity that can be used in denitrification models was proposed by Heinen (2006a).

27.4.4.3 Potential and In Situ Denitrification Activity

The effect of regulating parameters and the great variability of soil denitrification activity means that the soil potential activity measured in standard laboratory conditions must be distinguished from the real or in situ activity determined in natural or field conditions. A potential denitrifying activity measurement, or denitrifying enzyme activity (DEA), was proposed by Smith and Tiedje (1979) as the rate of N_2O production in the presence of acetylene from soil samples placed under anaerobic conditions and supplied with excess carbon and nitrate sources. These authors suggested that chloramphenicol should be used in DEA assays to inhibit synthesis of new denitrifying enzymes. This method in a standard form (Tiedje et al., 1989) is used with variations. Glucose can be replaced by a more efficient carbon source, such as succinate, for the denitrifying community (Heylen et al., 2006).

Chloramphenicol can disrupt the existing denitrifying enzymes and result in an underestimation of their activities (Brooks et al., 1992). Pell et al. (1996), therefore, proposed a method with different chloramphenicol concentrations to extrapolate the rate in the absence of this inhibitor while Murray and Knowles (1999) concluded that DEA essays should be carried out with just one, sufficiently low concentration. Other works demonstrate that DEA is not significantly affected by chloramphenicol (Simek et al., 2002; Yu et al., 2008) and confirm that DEA can be estimated using a short incubation without this inhibitor (Parry et al., 1999). Measured on soil slurries, DEA gives generally high values varying from 1 to 100 mg N kg^{-1} dry soil day^{-1} corresponding to several kg or hundreds of kg N ha^{-1} day^{-1} with a low variability for a given soil, while the denitrification rates in field conditions or on undisturbed soil cores are two to three orders of magnitude lower with a much larger variability (Parkin et al., 1987; Ullah et al., 2005).

Denitrifying activity can be usefully evaluated on undisturbed soil samples with water-saturated pore space and no limiting nitrate content in the absence of an added source of carbon. This can be considered to be the potential denitrifying rate of the microbial community in a soil in an undisturbed or slightly disturbed structural state, depending on the endogenous carbon compounds and organic matter mineralization in the soil (Heinen, 2006a). This type of activity used in denitrification models is generally significantly lower than the DEA activity measured on soil slurries. Burford and Bremner (1975) and Van der Salm et al. (2007) measured denitrification rates varying from 2 to 55 mg N kg^{-1} dry soil day^{-1} and from 10 to 70 mg N kg^{-1} dry soil day^{-1} on wet and homogenized soils using protocols similar to DEA, while Hénault and Germon (2000) estimated values on undisturbed and water-saturated soil cores with the nitrate not a limiting factor, varying from 1 to 30 kg N ha^{-1} day^{-1} corresponding to 0.4 to 12 mg N kg^{-1} dry soil day^{-1}.

27.4.4.4 Evaluation of Denitrification N Losses in Soils: Measurements and Models

An accurate evaluation of N losses due to denitrification is essential for understanding N cycling in the environment and for optimizing the use of nitrogen fertilizers in agriculture. There are two main approaches for evaluating N losses by denitrification: (1) Local and repeated gaseous loss measurements with integration over space and time. In order to take into account the temporal variability, denitrification losses are usually integrated over 1 year. (2) Estimation of the denitrification using models taking account of the regulating factors.

In a comprehensive synthesis of in situ denitrification measurements using acetylene, Barton et al. (1999) reported that denitrification in uplands with agricultural and forest soils varied between 0 and 239 kg N ha^{-1} $year^{-1}$ with a clear distinction between the two types of soils. Annual denitrification rates in forest soils ranged from 0 to 40 kg N ha^{-1} $year^{-1}$ with over 50% of the rates being lower than 1 kg N ha^{-1} $year^{-1}$, 80% lower than 10 kg N ha^{-1} $year^{-1}$, and a geometrical mean rate of 1.9 kg N ha^{-1} $year^{-1}$. In agricultural soils, denitrification losses varied from

0 to 239 kg N ha^{-1} $year^{-1}$ with only 10% of the rates being lower than 1 kg N ha^{-1} $year^{-1}$, 20% higher than 50 kg N ha^{-1} $year^{-1}$, and a geometrical mean rate of 13 kg N ha^{-1} $year^{-1}$. These orders of magnitude are confirmed by recent data on Dutch soils (Van der Salm et al., 2007) and by Hofstra and Bouwman's (2005) review using measurements based on chamber, soil core, and N balance techniques, with denitrification rates in agricultural soils from 0 to 341 kg N ha^{-1} $year^{-1}$, and higher values from the N balance techniques than from soil core measurements using acetylene.

In order to avoid meticulous and time-consuming denitrification measurements, a number of predictive models have been developed to evaluate denitrification losses in a range of situations. Some mechanistic models are useful for understanding denitrification mechanisms at a small scale (Smith, 1980; Sierra et al., 1995, Standing et al., 2007) but are inappropriate for evaluating denitrification in varied ecological situations. Many attempts have been made to evaluate denitrification at field scale using a statistical approach (Myrold, 1988; Jarvis et al., 1991; Weier et al., 1991), but these models are inadequate when used in situations other than those for which they were developed.

Simplified process models appear to be the most effective models for predicting denitrification in soils and more than 50 models of this type have been described (Heinen, 2006a). Rolston et al. (1984) proposed a simplified process model, which has been applied by several groups with some modifications (Johnsson et al., 1991; Hénault and Germon, 2000; Van der Salm et al., 2007). The NEMIS model, developed by Hénault and Germon (2000), has the general form: $D_A = D_P F_N F_W F_T$, where D_A is the actual denitrification rate (kg N ha^{-1} day^{-1}), D_P is the potential denitrification rate on undisturbed soil cores, and F_N, F_W, and F_T are dimensionless functions taking into account the effects of soil nitrate content, the WFPS, and the soil temperature. Values of this potential denitrification rate D_P include the availability of C, avoiding a specific function for available C. In this approach, D_P is defined by experimental measurements on soil cores and is assumed to be constant over the year or for part of the year during which organic matter availability does not change. The nitrate function F_N is defined as an apparent Michaelis–Menten function, F_W is an exponential function of WFPS as defined in accordance with Grundman and Rolston (1987) with a threshold allowing denitrification, and F_T is a classic van't Hoff temperature function. The NEMIS model can be applied subject to two main limiting conditions: (1) It requires the determination of a potential denitrification rate on undisturbed soil cores, which could be avoided if a clear relationship could be established between the potential denitrification rate and organic matter content and (2) NEMIS is highly sensitive to the F_W function: The main point of dispute over the validity of this water function in varying situations concerns the WFPS threshold allowing denitrification activity. Such models need to be calibrated before use, but they can be a powerful tool for evaluating denitrification in different situations (Heinen, 2006b) taking account of the variations due to the regulating factors over the year (Van der Salm et al., 2007). However, this type of model does not take into account the spatial variability characterized by hot spots of denitrifying

activity. Considering such a variability remains a key challenge for modeling denitrification, even if analysis methods for variations and spatial structures can be developed for denitrification activity (Groffman et al., 2009).

27.4.5 Greenhouse Gas Emissions by Denitrification

Denitrification is involved in nitrous oxide (N_2O) and nitric oxide (NO) emissions, two gases contributing to the greenhouse effect. Nitrous oxide is a potent and long-lived greenhouse gas (Prather et al., 1995). Its contribution to radiative forcing is estimated to $0.16 \pm 0.02\,W\,m^{-2}$ (IPCC, 2007), and its concentration in the atmosphere continues to increase at a rate of 0.2%–0.3% year^{-1} with an atmospheric concentration in 2005 of 319 ± 0.12 ppbv (IPCC, 2007). Nitric oxide and its derived product NO_2 are tropospheric precursors of ozone, the third largest contributor to positive radiative forcing. In the troposphere, NO and NO_2 concentrations are very variable, ranging from natural concentrations of a few ppb to 2 orders of magnitude higher in highly polluted environments (IPCC, 2001; Wang and Lu, 2006).

In soils, N_2O and NO are mainly produced by denitrification and by nitrification (Firestone and Davidson, 1989), while denitrification is also a sink for atmospheric N_2O. The same environmental factors affect the production of both nitrogen oxides (Davidson et al., 2000), but the respective contribution of denitrification and nitrification varies with these factors, mainly with aeration. In aerobic conditions nitrification is the main process producing both gases formed as by-products proportionally to the nitrification rate (Li, 2000) by a poorly understood pathway. In anaerobic conditions, NO and N_2O are produced by denitrification, which generally occurs in soil when the soil WFPS is higher than 60% (Davidson, 1991) and accounts for all the N_2O produced when the soil WFPS is 70% or higher (Bateman and Baggs, 2005). The ratio between these two gases can vary depending on the soils and the environmental conditions (Li, 2000; Garrido et al., 2002) with a significant relationship between the NO/N_2O ratio and WFPS (Davidson et al., 2000). Well-aerated soils are favorable to NO emissions, while wetter soils preferentially emit N_2O, which can be reduced into N_2 by denitrifying bacteria in anaerobic conditions. Among the environmental factors regulating denitrification, low pH and high nitrate concentrations are known to increase N_2O emissions while the relative availability of C and NO_3^- influence both the denitrification rate and the N_2O/N_2 ratio (Miller et al., 2008).

Emissions of N_2O and NO from soils can be directly evaluated by micrometeorological methods (Jambert et al., 1997; Laville et al., 1997; Magiotto et al., 2000) or by chamber methods, measuring the concentration of N_2O by gas chromatography with electron capture detection and NO by chemiluminescence (Garrido et al., 2002). Several models have been built using these data to forecast N_2O and NO emissions at different scales. While a statistical approach makes it possible to evaluate emissions using emission factors (Bouwman, 1996; Mosier et al., 1998; Boeckx and Van Cleemput, 2001; Bouwman et al., 2002a) as

in the IPCC recommendations for assessing national N_2O emissions (IPCC, 2006), N_2O and NO emissions can be also evaluated using other models based on a more mechanistic approach taking into account nitrification and denitrification kinetics and regulatory factors (Potter et al., 1997; Davidson et al., 2000). These models should provide better tracking of processes affecting gas production/consumption for drawing up mitigation methods at field or regional scales (Chen et al., 2008).

Among the most frequently used models for N_2O emissions, the NGAS model proposed by Mosier and Parton (1985) for predicting daily N_2O losses was initially a simple mechanistic model accounting for the effect of water, nitrate, and ammonium content in the soil on these emissions. It was developed to become NGAS-DAYCENT, the daily time step version of the CENTURY ecosystem model (Parton et al., 1996, 1998), and can simulate NO, N_2O, and N_2 trace gas fluxes.

The DNDC (DeNitrification–DeComposition) model proposed by Li et al. (1992) was initially developed for N_2O fluxes and CO_2 production and was extended to NO, CH_4, and NH_3 emissions (Li, 2000). It is mainly based on nitrification and denitrification kinetics and consists of two components taking into account the impact of regulating factors: (1) The first component includes climate, crop growth, and decomposition submodels predicting the changes in physical parameters and substrate concentration profiles based on ecological drivers; (2) the second component consists of nitrification, denitrification, and fermentation submodels and predicts trace gas fluxes based on soil environmental variables.

The N_2O emission (NOE) model proposed by Hénault et al. (2005) is a semiempirical algorithm that simulates the production and reduction of N_2O in agricultural soils through both the denitrification and the nitrification pathways. The advantage of this model is that it takes into account measurable biological N transformation rates in soils and only requires a limited number of equations and site-specific parameters. This model was validated using different data sets and integrated into a CERES crop model for regional estimation of N_2O emission (Gabrielle et al., 2006a, 2006b).

Davidson et al. (2000) proposed a model of soil emissions of N_2O and NO based on the "hole-in-the-pipe" (HIP) model (Firestone and Davidson, 1989) using two functions based on soil nitrogen availability and soil water content. Using a relationship between N_2O/NO ratio in emitted gas and soil WFPS they characterize a large part of the observed variation of these emissions.

Global N_2O emissions are presently evaluated at 17.7 Tg N–N_2O year^{-1}, with 11 Tg from natural sources and 6.7 Tg from anthropogenic sources (IPCC, 2007). These estimates with large uncertainties are likely to be revised just as previous estimates were (IPCC, 2001). However, they underline the important contribution of agricultural systems, which amounts to 4.1 Tg N–N_2O year^{-1}, with an emission factor estimated at 0.91% of the applied nitrogen (Bouwman et al., 2002b). The emissions estimated using this factor account for only a part of total emissions (Crutzen et al., 2007), and the respective contributions of denitrification and nitrification to the total emissions are still uncertain.

A similar global inventory of nitric oxide emissions from soils was established by Davidson and Kingerlee (1997) by dividing the surface of the earth into biomes. They concluded that the best current estimate of the global soil source was 21 Tg N year^{-1}, confirming the significant contribution of this soil source to global emissions and the largest emissions for tropical regions at 15.7 Tg N year^{-1}. A possible adsorption of NOx onto plant canopy surfaces might reduce these emissions to the atmosphere to 13 Tg N year^{-1}. The agricultural system contribution estimated at 5 Tg year^{-1} is much higher than the 1.8 Tg established by Stehfest and Bouwman (2006). The contribution of denitrification to these emissions is considered lower than nitrification but needs to be more precisely estimated.

27.4.6 Managing Denitrification in Soils

There are three main reasons for denitrification management in soils: (1) inhibiting or limiting denitrification as it contributes to N loss for agriculture and emission of greenhouse gases, (2) increasing denitrification as this helps by removing nitrates, which can contaminate surface and groundwater, and (3) reducing the N$_2$O/N$_2$ ratio of the denitrification end products to lower the emissions of N$_2$O.

The inhibitory effect of various compounds on soil denitrification has been tested (Heinemeyer, 1979; Yeomans and Bremner, 1985) without any significant applications. The consistency between denitrification estimates by direct measurement and N balance (Van der Salm et al., 2007) implies that the optimization of N fertilization and land management are the best ways to limit denitrification losses by (1) adjusting available N in soils to that required by the plants, (2) maintaining the unused nitrogen in the soil, (3) keeping the mineral nitrogen content in soils as low as possible during fallow periods, (4) managing the soil to avoid the conditions favorable to denitrification. Various methods have been developed to optimize N fertilization and limit N losses, mainly based on the N balance sheet and N mineral measurements (Meynard et al., 2002; Alvarez et al., 2004; Burns, 2006). The implementation of these methods can significantly reduce excessive N fertilization and N losses (Ju et al., 2009). However, in many situations, even with well-adjusted N fertilization, it is impossible in practice to keep the nitrate content in the leached water from cultivated soils below 50 mg L^{-1} (Beaudoin et al., 2005).

Denitrification can be managed on a larger scale by using the denitrifying properties of wetlands and riparian zones to reduce nitrate concentrations in surface water. Such areas can intercept water flow from agricultural runoff and are a favorable environment for denitrification prior to discharge into water bodies (Mc Clain et al., 2003; Ullah et al., 2005; Pinay et al., 2007). However, riparian zones can also provide conditions favorable to dissimilatory NO$_3^-$ reduction to NH$_4^+$ (DNRA), and the balance of nitrate removal between denitrification and DNRA has to be considered (Davis et al., 2008).

The denitrifying capacity of soil can be used for wastewater purification (Lance et al., 1976), in particular as a tertiary treatment method by infiltrating secondary wastewater for nitrogen elimination by coupling nitrification and denitrification (Idelovitch et al., 2003). Enhanced in situ denitrification is presented as an economically attractive process to decrease nitrate concentration in drinking water in rural areas by injecting a carbon substrate such as ethanol or acetate into the contaminated aquifer (Khan and Spalding, 2004). However, such processes have to be managed with great care to avoid clogging the aquifer pores (Mariotti, 1994).

Denitrification management may be a way of mitigating the emissions of N$_2$O. Limiting nitrogen fertilization to the levels required for the plants and avoiding an excess of reactive nitrogen in soils appears to be the first mitigation method to be implemented in order to limit denitrification intensity and N$_2$O emissions. Moreover, some soils appear particularly prone to N$_2$O emissions with a high N$_2$O/N$_2$ molecular ratio from denitrification (Hénault et al., 2001): Specific management of these areas, such as low or no fertilization and pH adjustment, could be a way of reducing the incidence of these emission hot spots. Another way could be a better use of legumes in plant rotation. Rochette and Janzen (2005) have reported low N$_2$O soil emissions when legumes are cultivated. Many N-fixing bacteria are denitrifiers and can reduce N$_2$O into N$_2$. Better management of symbiotic nitrogen fixation by legumes could be a way of managing denitrification and reducing N$_2$O emissions and therefore needs further study.

27.4.7 Conclusions

The global nitrogen cycle is subject to strong anthropogenic disturbance owing to increasing inputs of reactive nitrogen from fertilizer application, atmospheric deposition, enhanced biological nitrogen fixation (BNF) by cultivated legumes and intensive agricultural practices, which stimulate nitrogen transformation rates. Denitrification should be studied within the general framework of the N cycle, taking these disturbances into account. The close correlation between atmospheric CO$_2$ levels, temperature variations, and atmospheric N$_2$O concentrations over the past 60,000 years (Gruber and Galloway, 2008) raises questions about the contribution of available nitrogen in the global carbon cycle and highlights the need for complementary studies on the connection between biological N fixation, denitrification, and N immobilization in soil and biomass.

The N balance between nitrogen fixation and denitrification, which are both processes that control the reactive nitrogen content in soils and water, is a major issue, particularly for the terrestrial ecosystem. Even though the N balance, taking into account N inputs and losses and storage of reactive N, is considered to be globally neutral, there are considerable uncertainties in the various components of this balance (Gruber and Galloway, 2008); while data on N inputs in terrestrial ecosystems is well-defined, estimates of terrestrial N losses by denitrification are still too inaccurate because of the large variability of denitrification in soils. Methods to understand and manage this important step in the N cycle must be developed to improve its estimation in

the environment. There are two main objectives for the further development of denitrification models: Better integration of spatial and temporal variability in these models and the development of methods for spatial integration to evaluate denitrification on a large scale such as basins or regions. Moreover, while major research has been carried out on the regulation of denitrification intensity in soils, more recent data underline the importance of denitrification N losses in aquatic environments, in particular in riparian areas and rivers. This demonstrates a real need for a better evaluation of the components contributing to denitrification in such ecosystems.

Concerning the microbial denitrifying community, the major issue is the role of denitrifier diversity in ecosystem functioning, especially for N flows and N_2O emissions. Denitrifying bacteria in various environments seem to be extremely diverse but basic questions, such as the redundancy of populations and the consequences of population shifts within the denitrifying community and their effect on denitrifying activity, remain unanswered. In particular, our understanding of the role of the active population and its response to environmental factors is still limited by current methods and constitutes a real challenge for the next 10 years.

27.5 Nitrogen in the Environment

Peter M. Groffman

27.5.1 Introduction

While N is an extremely valuable and important nutrient within the soils of nearly all ecosystems on the globe (Vitousek and Howarth, 1991), it becomes a highly problematic pollutant once it leaves one ecosystem and moves into another. Given that human alteration of the global N cycle is extreme and dynamic (Galloway et al., 2004, 2008; Schlesinger, 2009), that there are multiple forms of N that can be considered as pollutants, and that there are multiple vectors of transport for these forms of N, it is not surprising that the topic of "N in the environment" is one of the most well studied and controversial in soil and environmental science.

There are multiple forms of N that are of concern in the environment. Galloway et al. (2003) present a useful framework for thinking about how "reactive (all forms of N other than N_2) N" is added to the environment as a by-product of human agricultural, waste disposal, and energy generation activity and then "cascades" through the environment causing air and water quality problems. Soils play a critical role in the N cascade. As described elsewhere in this volume, soils contain a huge reservoir of nonreactive, but potentially mobilizable organic N and several different pools of reactive N. Nitrogen dynamics in soils contrast sharply with the atmosphere, which is dominated by a vast pool of unreactive N_2, and with aquatic ecosystems, which are dominated by pools of dissolved organic and inorganic N and by interactions between sediments and the water column.

In this section, the author provides a brief review of how each of the key species of reactive N are produced, transformed, and transported in the environment and then provides a framework for site or ecosystem-scale evaluations of (1) is this site (ecosystem) a source of N to the environment (surrounding ecosystems) and (2) does this site (ecosystem) have the potential to absorb N, that is, function as a sink. This framework is based on the idea that we can best address N pollution problems in a "landscape-scale context," where a landscape consists of a range of ecosystems (e.g., different cropping systems, different forest types on different soils, wetlands, pastures) that can be viewed as either N sources or sinks and that are connected via hydrologic and atmospheric transport pathways (National Research Council, 1993; Jones et al., 2001; King et al., 2005). A landscape approach allows for reconciliation of the within-system benefits versus external pollution problems that are inherent in analysis of N pollution problems and provides a strong basis for evaluation and management of these problems in the field. My goal is to provide the reader with a series of questions, and an approach to answering these questions, that allow for evaluation of key N source, sink, and transport processes at any point, in any landscape.

27.5.2 Forms of N That Are of Concern in the Environment

Detailed descriptions of the forms and transformations of N can be found elsewhere in this volume and earlier in this chapter. Here, the author provides a brief discussion of why certain forms of N are of concern in the environment, how they are produced and/or consumed within ecosystems, and how they are transported between ecosystems (Table 27.4).

TABLE 27.4 Forms of N of Concern in the Environment

N Form	Sources	Dominant Transport Vectors	Environmental Effects
Nitrate (NO_3^-)	Fertilizer disturbance combustion (acid rain)	Groundwater	Drinking water pollutant Eutrophication
Ammonia (NH_3, NH_4^+)	Fertilizer Animal waste	Surface runoff Atmosphere	Drinking water pollutant Eutrophication
Nitrous oxide (N_2O)	By-product of multiple transformations	Atmosphere Groundwater	Greenhouse gas Ozone destruction
Nitric oxide (NO)	By-product of multiple transformations	Atmosphere	Ozone precursor
Dissolved organic N	By-product of natural decomposition	Surface runoff Groundwater	Possible Eutrophication

27.5.2.1 Nitrate

Nitrate is regulated as a drinking water pollutant (U.S. EPA, 1990) and is considered to be a prime agent of eutrophication in estuarine and coastal ecosystems (Ryther and Dunstan, 1971; Vitousek et al., 1997; Boesch et al., 2001; Rabalais et al., 2002). This ion is added directly to ecosystems in some fertilizer types and is produced via mineralization (conversion of organic N to NH_4^+) and nitrification (conversion of NH_4^+ to NO_3^-) of other fertilizer types and organic materials (e.g., plant detritus, manures, organic wastes). Nitrate is highly soluble and does not have a strong affinity for soil particles and is therefore readily transported in surface runoff and percolation. It is frequently the dominant form of N in percolating water and in aquifers.

Ecosystems tend to be sources of NO_3^- to the environment if they are heavily fertilized and/or highly disturbed. In many ecosystems, NO_3^- losses are prevented by competition between plants and microbes, primarily because nitrifying organisms do not compete well with plants and other microbes for NH_4^+ (Chapman et al., 2006). Therefore, NO_3^- loss occurs only where N inputs from mineralization of soil organic matter, fertilization, atmospheric, or hydrologic sources are high enough to satisfy plant and microbial demands for N or where some type of disturbance disrupts plant and microbial competition, allowing nitrification to occur (Aber et al., 1989). There are many types of disturbance that can cause this disruption. Disturbances to the plant community that induce NO_3^- losses include harvest of crops (Gold et al., 1990; Randall and Mulla, 2001), clear-cutting of forest vegetation (Bormann and Likens, 1979), insect outbreaks (Eshleman et al., 1998; Lovett et al., 2002; Lewis and Likens, 2007), and hurricanes (Schaefer et al., 2000; Bruland et al., 2008). The dominant soil disturbance that can stimulate NO_3^- losses is tillage but more subtle disturbances, for example, earthworm activity (Bohlen et al., 2004) or cultivation can also be important.

In recent years, considerable attention has been paid to atmospheric transport of NO_3^- (Holland et al., 2005). This NO_3^- is formed in the atmosphere from N oxides emitted by combustion processes and returns to earth in rainfall (wet deposition) or by surface deposition as particles and/or vapor (dry deposition). Rates of atmospheric NO_3^- deposition range from 5 to more than 20 kg N ha^{-1} year^{-1} worldwide (National Atmospheric Deposition Program, 2007). Recognition of the importance of NO_3^- deposition has led to concern about N "saturation" of natural (i.e., unfertilized) ecosystems, which has been linked to a variety of deleterious chemical and biological changes in temperate ecosystems (Aber et al., 1989).

Many ecosystems function as "sinks" for NO_3^- in the landscape. Ecosystems where the growth of plants and/or microbes is strongly N limited will take up NO_3^- that is added in fertilizer or that enters via atmospheric or hydrologic transport (Vitousek and Howarth, 1991; Chapman et al., 2006). Ecosystems with high actual or potential rates of denitrification (i.e., with significant volumes of anaerobic soil) function as very effective sinks for NO_3^- (Seitzinger et al., 2006). The location of "sink ecosystems" relative to sources (e.g., wet riparian zones located between intensively farmed uplands and streams) is often a critical determinant of the nature and extent of NO_3^- pollution problems in a landscape (Lowrance et al., 1984; Vidon and Hill, 2006). The capacity of groundwater to support denitrification is another critical (and highly variable) determinant of landscape-scale NO_3^- dynamics (Korom, 1992; Nolan and Stoner, 2000; Rivett et al., 2008). There also appear to be abiotic sinks for N in soil, likely caused by chemical and physical condensation reactions between organic matter, iron, and NO_3^- (Davidson et al., 1991; Fitzhugh et al., 2003; Colman et al., 2008).

The challenge in evaluations of NO_3^- pollution problems is to determine the location, strengths, and hydrologic and atmospheric connections between sources and sinks in the landscape. Procedures for making these determinations are described in Section 27.5.3.

27.5.2.2 Ammonia

Ammonia is likely the most common inorganic form of N in soils. Most N fertilizers are NH_3 (or urea, which rapidly degrades to NH_3) based and NH_3 is the first inorganic N form released in decomposition (mineralization). However, free NH_3 is rarely present in soils of low and moderate pH (i.e., <8.0). Under these conditions, NH_3 exists in a protonated form, NH_4^+, which has a strong affinity for negatively charged clay and organic matter particles and is therefore much less mobile than NO_3^-. Free NH_3 is quite toxic however, and both NH_3 and NH_4^+ can readily cause eutrophication in N-limited aquatic ecosystems. There is a vast flux of NH_4^+ in most soils via mineralization–immobilization turnover (Booth et al., 2005), but most of this NH_4^+ never leaves the surface horizons of the soil. In contrast to NO_3^-, NH_4^+ is seldom found in groundwater.

The dominant vector of NH_3 transport in the environment is atmospheric. In areas of intensive animal production, rates of NH_3 volatilization are high enough to cause significant loading (e.g., 40–50 kg N ha^{-1} year^{-1}) of adjacent ecosystems by NH_4^+ deposition (Asman et al., 1998; Pinder et al., 2008). Some of the

most dramatic concerns about N saturation of natural ecosystems have arisen in areas of intensive animal production (e.g., the Netherlands). Ammonium is also frequently transported in surface runoff, most commonly in soils that have been treated with organic wastes (Sims et al., 2005).

Similar to NO_3^-, many ecosystems have a high capacity to function as sinks for NH_4^+. In most cases, NH_4^+ is more conservative than NO_3^- because it is less mobile and because there can be strong physicochemical sinks for NH_4^+ on cation exchange sites and in the interlayer spaces of ammonium fixing clays.

27.5.2.3 Nitrous Oxide

Nitrous oxide is produced and/or consumed by several N transformation processes including nitrification, denitrification, and dissimilatory nitrate reduction to ammonia (DNRA). There is environmental concern about N_2O because it is a "greenhouse" gas, which can influence the earth's radiative budget and it plays a role in stratospheric ozone destruction (Mooney et al., 1987; Prather et al., 1995).

Identifying and quantifying sources of N_2O in the landscape is hindered by the high spatial and temporal variability of the dynamics of this gas (Folorunso and Rolston, 1984; Robertson et al., 1988; Parkin, 1993). This variability is caused by the fact that there are multiple processes that affect this gas and there are multiple factors influencing each of these processes.

A variety of approaches have been taken to conceptualize the factors influencing N_2O emissions from ecosystems. Brumme et al. (1999) presented a hierarchy of controls in which long-term change in state variables such as soil and vegetation type generates site to site variation, while short-term changes in physical and chemical conditions such as drying and rewetting and freezing and thawing events produce temporal variation in flux. Mosier et al. (1998) presented a "cradle to the grave" approach that accounts for emission of N_2O as N fertilizer added to agricultural fields moves across the landscape from crop fields to groundwater to streams to rivers to estuaries to the ocean, with emission of N_2O at each step. Tropical soils tend to have higher N_2O fluxes than temperate soils (Stehfest and Bouwman, 2006).

Although N_2O is readily consumed by several processes in soils, most notably by denitrification in wet soils, it is quite stable once it gets into the atmosphere. This stability contributes greatly to the environmental concern about this gas. High concentrations of N_2O are also common in groundwater (Hiscock et al., 2003; Clough et al., 2005). Similar to NO_3^-, wet soils with a high potential for denitrification should be considered to be potential sinks for N_2O (Blicher-Mathiesen and Hoffmann, 1999). In areas where N_2O-rich groundwater interacts with such soils, this potential could be important to landscape N_2O fluxes.

27.5.2.4 Nitric Oxide

Similar to N_2O, NO is a gas that is produced as a by-product of several soil N cycle processes, especially nitrification and denitrification. In contrast to N_2O however, NO is quite reactive and short-lived in the atmosphere. There is environmental concern about NO because it is a precursor to ozone in the lower

atmosphere and contributes to the formation of atmospheric NO_3^- deposition (Guenther et al., 2000). The highly reactive nature of NO makes it even more difficult to predict ecosystems that will be strong NO sources. However, similar to N_2O, ecosystems that are N rich are likely to produce relatively large amounts of NO (Davidson and Verchot, 2000). Wet ecosystems are likely to have a high potential to consume NO.

27.5.2.5 Dissolved Organic N

Dissolved organic N (DON) has generally not been considered to be of environmental concern. However, recent studies have shown that DON is a significant pathway of N loss from many natural (Michalzik et al., 2001) and agricultural (van Kessel et al., 2009) ecosystems that increases in response to N inputs (Pellerin et al., 2006; Brookshire et al., 2007; Fang et al., 2009). Moreover, much of the DON that leaves ecosystems is highly labile and can decompose to inorganic N and cause eutrophication problems in N-limited waters (Seitzinger et al., 2002; Wiegner et al., 2006). It is likely that DON will receive increased attention as an environmental concern in the near future.

27.5.3 Evaluating N Sources and Sinks and Hydrologic Connections in the Landscape

In this section, the author presents a series of questions that allow for evaluation of key N source, sink, and transport processes at any point, in any landscape (Table 27.5). Posing these questions serves two purposes. First, they are a convenient vehicle for summarizing the diverse sources of information on N dynamics that are relevant to evaluating "N in the environment" and second, they provide a practical basis for managing N pollution problems. Consider the landscape depicted in Figure 27.12. To evaluate N in this landscape we need to be able to identify which

TABLE 27.5 Criteria for Determining if a Site Is a Source or Sink of N in the Landscape

Criteria	Determinants
Is the site N rich?	Fertilized
	Fine texture
	Legumes
	Wet tropics
Is the site highly disturbed?	Disturbance of plant uptake (e.g., harvest)
	Stimulation of mineralization (e.g., tillage)
	Disturbance of links between plant and microbial processes (e.g., tillage)
Does the site have a high potential for denitrification?	Wet soil
	High organic matter (especially important in groundwater)
	Fine soil texture
	Well-structured soil (large aggregates with anaerobic centers)
Does the site have a high potential for NH_3 volatilization?	High pH (>8.0)

A—Upland source area
B—Riparian zone

1—Surface runoff
2—Perched water
3—Groundwater flow
4—Underflow or deep recharge
FIGURE 27.12 Conceptual diagram of a landscape showing different hydrologic flowpaths from uplands to riparian zones to streams. (Reprinted from Schnabel, R.R., W.J. Gburek, and W.L. Stout. 1994. Evaluating riparian zone control on nitrogen entry into northeast streams, p. 423–435. *In* Riparian ecosystems in the humid U.S.: Functions, values and management. Proc. Conf. March 15–18, 1993. Atlanta, GA. National Association of Conservation Districts, Washington, DC. Used with permission of National Association of Conservation Districts.)

ecosystems are sources of N, how different forms of N move from one ecosystem to the other and which ecosystems function as sinks for N. Note that Figure 27.12 does not show atmospheric transport. The following questions and text are designed to provide a basis for "thinking" about N in a landscape context and to point to key landscape-scale factors that should be considered in evaluating N in the environment.

1. Is this site (ecosystem) potentially a sink or source of N in the landscape?

There are several relatively simple factors (summarized in Table 27.5) that can be used to determine if a particular site is a "source" of N in the landscape. The primary factor is to determine if "this is an inherently N-rich site" where N supply via mineralization exceeds the capacity for plant uptake. In natural ecosystems, inherent N richness is strongly linked to soil texture and to a lesser extent to parent material. Ecosystems that develop on coarse-textured soils tend to have vegetation that exhibits adaptations to frequent water stress. These adaptations (e.g., thick cuticle) result in the production of low-quality plant litter that results in low rates of N availability (Pastor et al., 1984). Coarse-textured soils also hold less organic matter and support lower microbial biomass than fine-textured soils (Paul, 2007), which also reduces the inherent N richness of a site.

All fertilized ecosystems can be considered to be N rich, but there are marked differences in the N source strength of different fertilized ecosystems, for example, fertilized forests will tend to be much weaker sources of N in the landscape than fertilized agricultural fields. Much of this difference is related to the nature and extent of fertilization and to the disturbance regime

of the site, for example, fertilized agricultural sites lose more N than fertilized forests because they are more highly disturbed. In addition to fertilizer, sites subject to N inputs via symbiotic fixation by legumes, high rates of N deposition, or high rates of groundwater or surface runoff N loading should also be considered to be potential sources of N in the landscape. Tropical soils tend to be more N rich than temperate zone soils (Vitousek and Howarth, 1991).

Next to N richness, the dominant factor controlling if a site is an N source in the landscape is disturbance regime. There is a large body of literature describing the effects of disturbances ranging from clear-cutting to tillage to grazing to acid rain on N losses from natural and agricultural ecosystems (Foster et al., 1997; Randall and Mulla, 2001). It is important to note that not all disturbances foster N losses from all ecosystems. The effect of disturbance on N cycling is dependent both on the nature and extent of the disturbance and on properties of the ecosystem being disturbed, for example, clear-cutting of forests is more likely to produce N losses from inherently N-rich forests than from inherently N-poor forests (Vitousek et al., 1982). Disturbances that alter key components of the N cycle are most likely to cause N loss. Key disturbances of this type include anything that reduces plant uptake (e.g., clear-cutting, harvest, herbiciding, grazing, fire), stimulates microbial mineralization activity (e.g., tillage), or disrupts linkages between microbial mineralization and plant uptake (e.g., tillage, harvest, earthworm activity, fire). It is important to stress that the effects of disturbance on N loss are often transient and/or difficult to predict. For example, many disturbances that reduce plant uptake in the short term (e.g., clear-cutting reduces plant uptake for several months, prairie fires decrease plant uptake for several weeks), increase uptake in the mid and long term (years for clear-cutting, months for prairie fire).

In addition to criteria for predicting if a site is a source of N in the landscape (N richness, disturbance regime), there are several factors that can be evaluated to determine if a site is a potential "sink" for N. Obviously, if a site is inherently N poor (e.g., N-poor soils, young actively growing vegetation), it will have a high potential to absorb inorganic N and transform it into organic N forms that are of less environmental concern. In addition to considering N richness, it is important to consider if a site is particularly supportive of key processes, for example, denitrification, DNRA, that consume reactive N forms of environmental concern. There is particular interest in sites with high volumes of anaerobic soil, for example, wetlands, that have a high potential to support denitrification and/or DNRA (Burgin and Hamilton, 2007). Fine-textured soils tend to have higher potential to support anaerobic conditions and denitrification than coarse-textured soils. Well-structured soils, with large aggregates capable of supporting anaerobic centers also support denitrification.

Evaluation of site sink potential is complicated in several ways however. First, not all inherently N-poor sites will be effective sinks for N, for example, sites on coarse-textured soils transmit water so fast that N is not taken up by plants or microbes very effectively (Vidon and Hill, 2004). Second, it is important

to recognize that consumption of one N form of environmental concern can lead to production of another form of concern, for example, denitrification can convert NO_3^- into N_2O. Finally, there can be a big difference between the actual and potential sink strength of an ecosystem within a landscape. If an ecosystem with a high potential to act as an N sink is not situated in a position to receive N from landscape N sources, it will not function as a sink. This final factor is discussed below.

While, it is clear that there are several readily observable criteria (N richness, disturbance regime, wet soil) that can be used to predict if a site is an N source or sink in the landscape, it is also clear that there are numerous complicating factors that influence the nature and extent of source and sink strengths that motivate more sophisticated evaluation techniques. The most common techniques involve simulation modeling that synthesizes the diverse factors affecting N dynamics to produce an integrated depiction of the dynamics of N at a site. There are numerous site or ecosystem-scale models of N dynamics for both agricultural (Tonitto et al., 2007) and natural (Band et al., 1993) ecosystems. A review of these models, which vary widely in their approach, emphasis, complexity, and ease of application, is well beyond the scope of this chapter. The key challenge for landscape-scale assessments of "N in the environment" is the ease with which a particular model can be used to identify sources and sinks within the landscape and then to link these sources and sinks via hydrologic or atmospheric flows (Tague, 2009). Identifying multiple sources and sinks in a landscape is challenging to site or ecosystem-scale models because soil, plant, and management conditions can vary widely across the landscape (e.g., only a few models are capable of simulating N dynamics in both agricultural and natural components of the landscape). Linking sources and sinks via hydrologic or atmospheric flows with site or ecosystem-scale models is difficult because these models seldom consider transport processes at scales relevant to internal N dynamics. Some efforts at true landscape-scale modeling of N dynamics are described below.

2. How does N enter and/or leave this site via hydrologic or atmospheric vectors?

Once we have determined if a site has an inherent potential to function as a sink or source of N in the landscape, we need to examine the nature and extent of the connections between this site and adjacent landscape components. The first part of this examination relates to the way that water moves into, through, and out of a site and to the potential of a site to absorb or transmit N to the atmosphere.

Hydrologic transport into, through, and out of a site is influenced primarily by soil texture, structure, and drainage and by slope, properties that are discussed extensively elsewhere in this volume. For the purposes of this chapter, our objective is only to highlight key properties that predict the hydrologic nature of a site as the basis for more detailed investigations (Table 27.6).

Sites with coarse soil texture have a high capacity for infiltration relative to sites with fine texture. As a result, coarse-textured soils are likely to produce leaching and movement of

TABLE 27.6 Critical Variables Affecting the Movement of N into, through, and out of a Site

Variable	Status	Results
Texture	Coarse	Infiltration—movement to groundwater
	Fine	Surface runoff
Structure	Well	Infiltration—movement to groundwater
	Poor	Surface runoff
Drainage	Well	Infiltration—movement to groundwater
	Poor	Surface runoff
Soil cover	High	Infiltration—movement to groundwater
	Low	Erosion by wind and water
pH	High	NH_3 volatilization
	Low	NH_3 stabilization as NH_4^+
		Potential for high yield of N_2O and NO

N to groundwater, while fine-textured soils are more likely to produce movement of N in surface runoff. Texture effects on infiltration are strongly modified by soil structure and cover, both of which increase the capacity for infiltration. Soil drainage class, which is controlled by the height of the water table in the soil profile, is a good predictor of water movement into and out of a site to the extent that saturated (more poorly drained) soils are less able to absorb incoming water. Slope has obvious effects on the transmission of incoming water.

The soil variables that most strongly influence the potential of a site to transmit N via atmospheric vectors are soil cover and pH. Soil cover strongly influences the potential of a site to have wind erosion. Sites with high soil pH (>8.0) have a high potential to produce NH_3 gas via volatilization. Sites with low soil pH (<5.0) have a relatively high potential to produce N_2O and NO.

3. Where does this site sit in the landscape?

The juxtaposition of N sources and sinks in the landscape is clearly a major determinant of overall landscape N flux. Figure 27.12 illustrates why riparian forests have been a major focus in research on controlling N outputs from agricultural watersheds (Lowrance et al., 1984; Vidon and Hill, 2006), that is, the presence of an ecosystem with a high potential to act as an N sink (an unfertilized forest, with wet soil) in a position to absorb N moving in both surface runoff and groundwater can have a big impact on watershed N output.

Figure 27.12 also illustrates the difficulties in carrying out quantitative landscape-scale evaluations of N flux. These evaluations require models capable of depicting internal and input/output N dynamics in diverse ecosystems as well as landscape scale hydrologic processes (Tague, 2009). These requirements are a challenge to modelers who need to balance the need for detail in their models with the need to be comprehensive. These requirements also demand large amounts of high-resolution input data on soil, hydrologic, and ecological conditions (Baker et al., 2007). Linking simulation models with geographic information systems to carry out landscape-scale assessments of N flux is rapidly developing into a major approach for managing N in the environment (Groffman et al., 2009).

4. What are subsurface conditions in this site?

Landscape-scale assessments of N flux must consider subsurface processes. The most common concern about N in the environment is NO_3^- pollution of groundwater. Figure 27.12 shows the importance of considering the physical, chemical, and biological conditions of the subsurface material that NO_3^--laden groundwater passes through as it moves through the landscape. While some studies have found high potential and/or actual denitrification in subsurface material others have found little or no activity (Korom, 1992; Rivett et al., 2008).

Most of the uncertainty around subsurface processes concerns the presence of energy sources to support microbial processes. A major challenge for the next few years is to develop a basis for predicting N dynamics in the subsurface based on factors such as soil type, geologic setting, or regional hydrologic conditions. There is also an important need to determine if there are functional links between groundwater and surface soil processes.

27.5.4 Conclusions

It is clear that we have much of the information needed to assess the dynamics of "N in the environment." Our detailed knowledge of N cycle processes (described in other sections of this chapter) allows us to predict and manage internal N dynamics in ecosystems. The challenge, however, is to apply this knowledge at the landscape and watershed scales, which is where we need to assess and manage N pollution problems. In a conceptual sense, we need to develop the ability to "think" at larger scales; to consider landscape units such as those depicted in Figure 27.12 as our objects of study rather than the single crop fields or forest stands that have been the traditional focus of much soil research. In a practical sense, we need to modify existing models and/or develop new models that are capable of dealing with the wide range of sites and ecosystems within a landscape and that are capable of incorporating true landscape-scale hydrologic and atmospheric transport phenomena. These conceptual and practical challenges will likely be quite important in many areas of soil science over the next couple of decades.

28.1 Cultivation-Independent Detection of Genes Present in Soil Bacteria

Guo-Chun Ding

Holger Heuer

Kornelia Smalla

The development of methods to extract DNA directly from soil samples opened new dimensions of studies on microbial communities in soil. The molecular analysis of soil DNA can provide information on the microbial community composition or on the presence and on the relative abundance of functional genes, for example, of genes involved in N-cycling, antibiotic resistance genes, degrading genes, or plasmid replicon-related sequences.

DNA-based analysis of soils led to the discovery of many taxa that are abundant in soils but had not been studied before as they do not easily form colonies on plates. This chapter is exclusively devoted to the detection of genes in DNA directly extracted from soil. Crucial prerequisites of the cultivation-independent detection of genes in soil are appropriate sampling strategies and DNA extraction protocols. Therefore, the subsequent two paragraphs will briefly address these topics before discussing the potentials and limitations of methods for targeted or untargeted detection of genes.

28.1.1 Sampling and Sample Processing

The adequate sampling design depends on the hypotheses to be tested and often preexperiments might assist in determining the numbers of samples to be analyzed. Sampling of soil requires a

careful design of a strategy considering the estimated heterogeneity of the soil system and the expected variability (Van Elsas et al., 2002; Smalla and van Elsas, 2010). To overcome variability due to field heterogeneity, composite samples of soil taken from a plot or a field, often in a number of replicates, were analyzed in many of the studies. The main reason for analyzing composite samples is that the sample should be in a representative manner reporting on the structural and functional diversity of a soil under a particular treatment and on the variation among replicates of the same treatment. Each composite sample may consist of several soil cores taken from a plot in a randomized fashion. Mixing of the soil is usually achieved by sieving the material of the various soil cores through a 2 or 4 mm mesh size. A subsample from each composite sample is then used for the analysis. However, the investigation of composite samples may obscure a meaningful biological variation. Thus, in studies aiming to explore field, plot or microscale variability characterization of independent single samples would be required (Sliwinski and Goodman, 2004; Becker et al., 2006).

28.1.1.1 Nucleic Acid Extraction from Soil Samples

Thirty years after the first paper on the extraction of DNA from soil had been published by Torsvik (1980), obtaining nucleic acids from soil matrices that are suitable for molecular analysis remained a challenge (for review; Van Elsas et al., 2000). None of the protocols for DNA extraction from soil seems suitable for all kinds of soils, in particular for soils originating from contaminated sites. Commercial kits for total DNA extraction from soil facilitated largely the procedure in particular in view of a simplification and miniaturization of the method. Soil DNA extraction kits are often less time-consuming and more efficiently remove coextracted humic acids. Nucleic acids can be extracted directly either from the soil matrix or from a microbial pellet obtained after dislodging microbes associated with soil particles or plant roots and subsequent centrifugation. The first protocol for direct extraction of DNA from soil was published by Ogram et al. (1987) and is based on in situ lysis of microbial cells in the presence of the environmental matrix. The second approach, also termed indirect method, was pioneered by Torsvik (1980) and Holben et al. (1988) and involves the extraction of nucleic acids from the microbial fraction. The recovery of the microbial fraction from soils commonly involves repeated homogenization of soil resuspended in aqueous solution and differential centrifugation steps as originally suggested by Fægri et al. (1977). However, protocols differ considerably with respect to the solutions used to break up soil colloids and dislodge surface-attached cells, which adhere to surfaces by various bonding mechanisms such as polymers, electrostatic forces, and water bridging, and of different strengths (Bakken and Lindahl, 1995; Van Elsas et al., 2000). This approach might preferably be used for obtaining nucleic acids from soil adhering to roots (rhizosphere), problematic soils (soils with a high content of humic acids or contaminants), or to obtain high-molecular DNA for generating fosmid or BAC libraries. Homogenization is usually achieved by shaking soil suspensions with gravel or blending, for example, with a Stomacher lab blender. Although a complete dislodgment of cells seems impossible, it is important that cells bound to soil particles with different degrees of strength are released with similar efficiency. A clear advantage of the indirect approach is that nucleic acids recovered are less contaminated with coextracted humic acids, DNA of nonbacterial origin, or extracellular DNA (unless extracellular DNA is tightly adsorbed to microbial cells). In comparison with the indirect method, the direct DNA extraction approach is less time-consuming and much higher DNA yields are achieved (Van Elsas et al., 2000), which might, however, contain considerable amounts of coextracted humic acids.

A crucial step for the recovery of representative DNA that mirrors the genomes of all microbes present in a soil sample (Moré et al., 1994; Miller et al., 1999) is the efficient lysis of the bacterial, archaeal, and fungal cell walls. Cell lysis can be achieved by mechanical cell disruption and by enzymatic or chemical disintegration of cell walls, or a combination of these methods is often used. The efficiency of the different methods used for cell lysis might influence not only the yield but also the presence of genomic DNA of cells difficult to lyse (resting stage, e.g., dwarf cells or spores). However, obviously the strength of lysis needs to be a trade-off as too rigorous lysing methods might shear DNA released from cells that are easy to lyse. Therefore, high-molecular-weight DNA is an important criterion when evaluating and comparing different protocols because sheared DNA can cause PCR artifacts and is not suitable for direct cloning of large DNA fragments. To obtain large DNA fragments is particularly important for generation of large insert libraries (e.g., fosmid or BAC libraries). In plug lysis of the microbial pellet and pulse field gel electrophoresis is most frequently used to obtain large DNA fragments (Robe et al., 2003). The complete removal of coextracted humic acids is critical for the subsequent molecular analysis as humic acids were shown to interfere with DNA hybridization, restriction enzyme digestions, and PCR amplification (Tebbe and Vahjen, 1993). The DNA yield might vary considerably for different DNA extraction kits used for the same soils. As directly extracted DNA can be of different origin, it is recommended to estimate the DNA yield not only on ethidium bromide–stained agarose gels or by measuring the ratio 260/280 but also by determining the 16S or 18S rRNA gene copy numbers by quantitative PCR. A recently performed comparison of two frequently used soil DNA extraction kits revealed that the 16S rRNA gene copy numbers were approximately two orders of magnitude different. Differences in DNA yield might be no problem if bacterial, archaeal, or fungal ribosomal gene fragments are amplified by PCR. However, if the analysis is targeting less abundant taxa or genes that are carried only by a small proportion of the microbial community, then the difference in yield will be critical. Last but not least, it should be stressed that strict precautionary measures need to be taken to prevent contamination of the DNA during the extraction either directly from soil or from the microbial pellet. In particular, when PCR amplification is used to amplify a target gene that occurs less frequently,

for example, antibiotic resistance genes or transgenic DNA in soil, the extraction of DNA, preparation of PCRs, and analysis of PCR products need to be strictly separated.

28.1.2 Targeted Detection of Genes in Nucleic Acids from Soil

28.1.2.1 Detection of Genes Providing Information on the Structural Diversity

PCR-based amplification of 16S, 18S rRNA, or ITS gene fragments from soil DNA and their subsequent analysis either by cloning and sequencing, direct sequencing, or by fingerprinting methods are most frequently used to study the composition of Bacteria, Archaea, or Fungi in soil. A considerable advantage is the rapidly growing database of rRNA gene sequences, which contains presently more than 710,000 long high quality 16S rRNA gene sequence entries deposited in Ribosomal Database (http://rdp.cme.msu.edu, release 10.26). A disadvantage of using rRNA gene fragments is that bacteria possess different numbers of rRNA operons that are assumed to reflect different ecological strategies of bacteria (Klappenbach et al., 2000) and that sequence heterogeneity of the different operons might occur (Nübel et al., 1996; von Wintzingerode et al., 1997). Alternative markers such as the gene coding for the σ factor *rpoB* or *gacA* have been suggested since these genes are present only as a single copy and were shown to allow a higher resolution between species (Dahllöf et al., 2000; Costa et al., 2007). However, no matter which gene is targeted, one major limitation that remains is that gene fragments of less common populations are often not represented in clone libraries or fingerprints, especially when primers targeting all bacteria are used for amplification. Bent and Forney (2008) termed this problem "the tragedy of the uncommon" and critically discussed in this context the use of diversity indices. The application of group- or genus-specific primers targeting the 16S rRNA gene can assist in studying less common populations in soil (Heuer et al., 1997, 2001; Costa et al., 2006a; Weinert et al., 2009). In order to be detected by PCR-based methods, the gene copy number of a population should be above 100 or 1000 cells g⁻¹ of soil as usually one-hundredth or less of the DNA extracted from a gram of soil is used as template for PCR amplification. Thus, the diversity of uncommon populations in soil might become only detectable after soil enrichment steps.

The 16S or 18S rRNA gene or ITS fragments amplified from total community DNA with Bacteria-, Archaea-, or Fungi-specific primers were traditionally characterized by cloning and sequencing. Janssen (2006) compared 32 different clone libraries generated from various soils and found that 16S rRNA gene sequences from soil DNA could be affiliated to 32 phyla but that the dominant phyla in the libraries belonged to nine phyla only, that is, the Proteobacteria, Acidobacteria, Actinobacteria, Verrucomicrobia, Bacteroidetes, Chloroflexi, Planctomycetes, Gemmatimonadetes, and Firmicutes. Interestingly, the phylum Firmicutes, including the classes Bacilli and Clostridia that were considered to be typical soil bacteria, contributed up to only 2% of

the sequences in the clone libraries. However, the composition of the clone libraries, that is, the relatively low abundance of the Firmicutes, might have been strongly affected by DNA extraction biases as mentioned above. Another rather recent methodological development is the use of pyrosequencing to study the diversity of bacterial 16S rRNA gene fragments PCR amplified from soil DNA (Roesch et al., 2007; Fulthorpe et al., 2008; Jones et al., 2009). These studies provided the largest datasets on rRNA gene sequences obtained for soil so far. Furthermore, these data indicated that the number of species per gram of soil estimated by Gans et al. (2005) was an overestimate. More importantly, in-depth analysis of soil microbial diversity by sequencing was shown to be no longer impracticable as suggested by Gans et al. (2005). However, despite the enormous amount of data acquired by pyrosequencing, 10,000 sequences are still a very small fraction of >10⁹ bacteria living in 1 g of soil. Therefore, more attention should be paid to statistical exploration of these datasets. First of all, how well does the dataset reflect the real diversity? Table 28.1 demonstrates the relationship among the relative abundance of a species, the total number of sequences, and the chance to detect this species. For example, the relative abundance of a species needs to be at least 0.03% to be detected in a sample of 10,000 sequences with a chance of 95%. This corresponds to more than a million cells per gram of soil. However, many soil bacteria will have a lower abundance, at least temporarily or locally. A second important question is how well the dataset from pyrosequencing can represent the community structure. The simulation results in Table 28.2 show that there will be a significant error in predicting the relative abundance of rare species. A relative species abundance of less than 0.01% will be predicted with an error of more than 100%. Obviously, it is still very difficult to reliably predict the community structure also with respect to minorities.

To study spatial and temporal variation of microbial communities in relation to environmental factors, perturbation, or experimental treatment, multiple sample analysis is essential (Muyzer and Smalla, 1998; Smalla et al., 2001, 2007; Forney et al., 2004; Kowalchuk et al., 2006). For this purpose, approaches based on cloning and sequencing or direct sequencing of 16S rRNA gene fragments amplified from community DNA are still

TABLE 28.1 Relative Abundance of a Species That Is Needed to Detect Its Sequence within a Total Number of Sequences at a Specified Likelihood, Based on a Poisson Distribution

Likelihood of Detection	Minimal Relative Abundance (%)			
	Total Number of Sequences			
	10	100	1,000	10,000
0.1	1.0	0.11	0.01	0.001
0.3	3.5	0.36	0.04	0.004
0.5	6.7	0.69	0.07	0.007

0.99	36.9	4.50	0.46	0.046

TABLE 28.2 Uncertainty to Predict the Community Structure from Pyrosequencing Data (Coefficient of Variance from 1000 Simulations to Sample Nine Species of a Particular Relative Abundance)

Relative Abundance (%)	Error of Species Abundance Prediction (%)			
	Total Number of Sequences			
	1,000	2,000	10,000	20,000
10	9.7	6.9	3.1	2.2
1	30.9	21.5	9.5	7.0
0.1	95.4	66.8	30.8	21.9
0.01	262.1	209.6	101.7	71.7

too costly and labor intensive, especially for terrestrial habitats of a large microbial diversity. Although a rapid development in the field of high-throughput sequencing techniques is witnessed making pyrosequencing more and more affordable and feasible, the use of molecular fingerprinting techniques like denaturing gradient gel electrophoresis and temperature gradient gel electrophoresis (DGGE and TGGE; Muyzer and Smalla, 1998), single-strand conformation polymorphism (SSCP; Schwieger and Tebbe, 1998), terminal-restriction fragment analysis of 16S ribosomal genes or fragments amplified from total community DNA, that is, terminal-restriction fragment length polymorphism (T-RFLP; Liu et al., 1997; Osborn et al., 2000), or automated rRNA intergenic spacer analysis (ARISA; Ranjard et al., 2001) remains the state of the art here (Table 28.3). The molecular fingerprinting techniques based on 16S or 18S rRNA gene or ITS fragments or on alternative marker genes amplified from total community DNA still represent the best compromise between the number of processed samples and the level of information that is obtained. An advantage of microbial community fingerprint analysis is the quick overview of the composition of dominant sequences amplified, which reflect the relative abundance of bacterial populations or a specific taxonomic group. When combined with the analysis of sequences of differentiating bands, information on the phylogenetic placement can be rapidly gathered. Recently, Smalla et al. (2007) showed that the analysis of 16S rRNA gene fragments amplified from soil DNA with bacteria-specific primers by means of DGGE, SSCP,

or T-RFLP resulted in comparable results. Although the target regions varied, DGGE, T-RFLP, and SSCP analyses all led to similar clustering. In this study, little variability in the bacterial community composition of the four replicate composite samples analyzed per soil was observed while significant differences among the different soils were found that mirrored soil physicochemical properties such as pH, clay content, or organic C. In a continental-scale study, including 98 soil samples from North and South America, T-RFLPs of 16S rRNA gene fragments amplified from total community DNA were used to compare bacterial communities across sites (Fierer and Jackson, 2006). The study showed that the composition of soil bacterial communities differed between ecosystems and that most of the differences could be explained by soil pH.

The resolving power of current PCR-based community fingerprinting methods can be considerably increased using taxon-specific primers. During the PCR with universal primers, a particular target sequence should be present at least at about 0.1%–1% of the total target sequences to be amplified and appear as a visible band in a fingerprint. To analyze the less common ribotypes and also reduce the complexity of the patterns, nested or seminested PCR approaches with taxon-specific primers have been quite successfully used (Heuer et al., 1997; Gomes et al., 2001, 2005; Boon et al., 2002; Salles et al., 2002; Garbeva et al., 2003; Freitag et al., 2005; Costa et al., 2006a, 2006b; Weinert et al., 2009). Different studies that compared DGGE patterns based on 16S rRNA gene fragments amplified from DNA or cDNA (following RNA extraction and a reverse transcription step) from soil, reported that DNA- and RNA-based fingerprints of soil bacterial communities are often rather similar (Nicol et al., 2003; Gomes et al., 2005).

Recently, 16S rRNA gene fragments amplified from soil DNA were also analyzed by so-called PhyloChips that enable the parallel detection of more than 8700 operational taxonomic units (OTUs) and the ability to identify individual OTU varying by five orders of magnitude in abundance (Brodie et al., 2006; DeSantis et al., 2007). Typically, more than 2000 OTU can be detected in soil DNA. In the study by DeAngelis et al. (2009), the rhizosphere effect was studied by PhyloChip analysis. OTUs responding to the root exudates were detected in 17 of the 44 phyla. PhyloChip analysis of 16S rRNA gene

TABLE 28.3 Molecular Techniques Used to Compare and Analyze Microbial Communities from Soil

Technique	Principles	Reference
DGGE and TGGE	PCR-amplified fragments of 16S/18S rRNA, *rpoB*, *gacA*, or other genes are separated based on their melting in a denaturing gradient formed by chemicals (DGGE) or temperature (TGGE)	Muyzer and Smalla (1998)
SSCP	Digestion of one DNA strand of PCR-amplified fragments, and electrophoretic separation based on the sequence determined conformation of the remaining single strand	Schwieger and Tebbe (1998)
T-RFLP	PCR amplification of gene fragments using fluorescently labeled primers, cutting off the labeled terminal fragments using restriction enzymes, and separation on a sequencer based on the size of the terminal fragments	Liu et al. (1997)
ARISA	PCR amplification of intergenic spacers of ribosomal operons using fluorescently labeled primers targeting rRNA genes, and separation on a sequencer based on the size of the fragments	Ranjard et al. (2001)
Pyrosequencing of rRNA genes	Massive sequencing of PCR-amplified 300–500 base fragments by synthesizing a complementary strand and detection of pyrophosphate release on nucleotide incorporation	Roesch et al. (2007)

fragments enables a comparison of multiple samples and a determination of taxa responding to biotic or abiotic factors. The great advantage of PhyloChips compared to other fingerprinting methods is that information on the taxonomic affiliation of these responders can be obtained.

However, the molecular fingerprints described above provide no quantitative data on the abundance of the taxa detected. Here, the real-time determination of 16S rRNA gene copy numbers, for example, of Bacteria or Archaea or of specific groups is the method of choice. Particular characteristics of the 16S rRNA gene, such as those caused by the presence of different numbers of rRNA operons per genome (from 1 to up to 15), in different species prevent that the copy number determined can be directly translated to cell number. Real-time PCR formats that are most commonly used are SYBR Green detection and TaqMan probes. SYBR Green binds unspecifically to all double-stranded DNA, and, thus, product formation is monitored by an increased fluorescence. In contrast, the TaqMan probe assay is based on the specific binding of the double-labeled probe (quencher and reporter dye) to a target sequence and the cleavage of the probe by the Taq polymerase endonuclease activity. Upon cleavage, the reporter dye is no longer quenched and the signal can be detected. Again, a sufficient abundance of the target sequence and absence of potential PCR-inhibiting substances, such as coextracted humic acids, need to be considered for a reliable real-time PCR detection from soil.

28.1.2.2 Targeted Detection of Functional Genes

PCR-based detection of functional genes in soil has widely been used in several studies. The presence of different functional genes in soil bacteria has usually been studied by PCR amplification from total DNA and subsequent cloning and sequencing. If sufficient amounts of PCR products can be obtained, the analysis of PCR amplicons by cloning and sequencing or by molecular fingerprints can provide information on the diversity of respective genes, for example, *pmoA* (Horz et al., 2001), *dsr* (Schmalenberger et al., 2007), bacterial or archaeal *amoA* (Nicol et al., 2008; Jia and Conrad, 2009), *ndo* genes (Gomes et al., 2007; Flocco et al., 2009), or chitinase genes (Metcalfe et al., 2002).

If the gene targeted is present above a critical detection threshold, then its presence can be quantified by real-time PCR (Heuer and Smalla, 2007; Hai et al., 2009; Heuer et al., 2009; Schauss et al., 2009). In particular, the development of real-time PCR assays enabled studies relating gene abundance to various different biotic or abiotic factors. Again the detection limit is an important issue. Only if gene copies occur with more than 10^5–10^6 copies per gram of soil, amplicons visible in ethidium bromide–stained agarose gels are obtained. The detection limit is comparable for real-time PCR. Although SYBR Green is widely employed for the detection of functional genes by quantitative PCR, the use of TaqMan probes might increase specificity and sensitivity of the system. In many studies, the copy number determined is related to a gram of soil or even microliter of DNA. However, it is strongly recommended that the copy number determined is related to 16S rRNA gene copy numbers to overcome biases caused by uncertainties of the total soil DNA composition. Although comparable amounts of DNA are obtained per gram of soil, the number of 16S rRNA gene copy numbers might vary considerably (Heuer et al., 2009). If the gene targeted is less abundant in the soil population, then it is recommendable to increase the sensitivity of its detection by Southern blot hybridization. Even if amplicons are not visible on the agarose gel, they can be detected by means of hybridization with digoxigenin or ^{32}P-labeled probes. Although the data obtained are at the most semiquantitative, the sensitivity of gene detection is often increased by two orders of magnitude. In addition, by choosing the stringency of the hybridization conditions, sequence specificity of the signal can be confirmed. The presence of different functional genes in soil bacteria has been studied by PCR amplification from total DNA and subsequent analysis by Southern blot analysis, for example, *merA*, *trfA* (Smalla et al., 2006), *nahA*, *nahH*, and *phnAc* (Gomes et al., 2005, 2007).

The spectrum of primers is also a very important issue as the diversity of many genes is still unknown and many novel sequences could be frequently found from environmental samples. The potential for microbial degradation of polycyclic aromatic hydrocarbons (PAHs) in the environment is of major interest due to the bioaccumulation and toxicity of these compounds. The diversity of PAH-degrading genes in soils and how it is influenced by different soil types or their history and type of pollution is not yet well explored, because the existing primer systems have severe limitations. In Table 28.4, published primers that detect PAH-ring-hydroxylating dioxygenase genes are summarized. Most of the primers target only a rather narrow range of sequences, for example, *nahAc* or *phnAc* type sequences, or only genes from Gram-negative bacteria. One primer system could detect dioxygenase genes of both Gram-positive and Gram-negative bacteria, but the specificity is broader than PAH dioxygenases and the short amplified fragment does not resolve much of the diversity (Ni Chadhain et al., 2006). To overcome these limitations, recently accumulating sequence data need to be used to develop better primer systems to determine the diversity and abundance of PAH-ring-hydroxylating dioxygenase genes of soil microbial communities.

28.1.3 Nontargeted Detection of Genes

Functional genes have been detected in soil DNA by the so-called functional arrays. However, the performance of microarray hybridization from complex environments such as soil has to be carefully evaluated and obviously a number of technical challenges need to be overcome before this technique can be fully exploited. A microarray with 100 functional genes was used by Wu et al. (2001) to systematically study the specificity, sensitivity, and quantification of microarray hybridization with DNA from complex environmental samples. When environmental DNA is used without prior PCR amplification, this seems to be the most difficult challenge. The level of detection is 1,000- to 10,000-fold lower than with PCR amplification (Wu et al., 2001). In order to achieve a comprehensive investigation of functional

TABLE 28.4 PCR Systems to Study the Diversity and Abundance of PAH-RHDα Genes in Soil

Primers	Target Genes	Amplicon Size (bp)	Sample Sources	Sample Type and Analysis	Reference
NAPH-1F/-1R; NAPH-2F/-2RGC	*nahAc*, *phnAc*, *nagAc*, and *ndo* (Gram-negative bacteria)	896; 740	PAH-contaminated mangrove sediments (Brazil) or soils (Maritime Antarctic)	Total community DNA, DGGE, and clone library	Gomes et al. (2007)

genes, so-called GeoChip microarrays containing over 24,000 probes covering more than 10,000 genes distributed among more than 150 functional groups involved in nitrogen, carbon, sulfur, and phosphorus cycling were recently employed for soil studies (Gentry et al., 2006; Wu et al., 2006; He et al., 2007). The direct hybridizations were, however, not very sensitive, and to increase the sensitivity of the approach, a preamplification step (e.g., using rolling circle amplification) is now included. Despite numerous challenges that need to be solved, the GeoChip will be a powerful tool that allows linking functional microbial dynamics to particular ecosystem processes. Probe development, hybridization quality, and data evaluation are crucial steps for an appropriate use of DNA microarrays to study the soil microbiota. The GeoChip was applied to study N- and C-cycle genes in DNA extracted from soil taken from different sites in the Antarctic (Yergeau et al., 2007). The N- and C-cycle genes detected differed significantly across sampling locations and vegetation types. However, DNA microarrays cannot generate information on new sequence types, and, thus, only the breadth of known functions can be assessed (Yergeau et al., 2007). A recent study of Suenaga et al. (2009) gives an idea on the severity of this limitation. They created a metagenomic library with DNA extracted from activated sludge and sequenced those clones with extradiol dioxygenase activity. By sequence analysis, they found that most of these clones (36 of 38) contained complete aromatic degradation pathways that shared low similarity to those found in known cultured bacteria metabolizing aromatic compounds. Having learned that soil bacterial communities can be extremely diverse, it will be a challenge to include all potentially important genetic variants of a particular soil function on a microarray. Furthermore, the abundance of most bacteria may be below the detection limit of microarrays, some of them having the potential to take over important functions when environmental conditions are advantageous for them. To increase the sensitivity, community DNA was frequently subjected to whole-genome amplification before microarray analysis.

Another nontargeted approach is cloning large fragments of environmental DNA into fosmid or BAC vectors and subsequent screening of the metagenomic libraries. Metagenomics offers access to functional genes in the soil microbiota and thus to novel bioactive products (Sjöling et al., 2007). This approach has been successfully applied to recover DNA coding for so far unknown enzymes or antibiotics directly from soil DNA (Rondon et al., 2000; Gillespie et al., 2002; Sjöling et al., 2007). However, despite the vast potential of this approach, several methodological challenges remain to be solved. To obtain sequence information of particular uncultured taxa, which are assumed to be abundant in the soil sample, in a first step, specific primers are used to identify the clones carrying the respective genes, either based on 16S rRNA or even on functional genes. Using this approach, genomic fragments of uncultured Acidobacteria or Archaea could be obtained and subjected to sequence-based gene detection (Ochsenreiter et al., 2003; Treusch et al., 2005; Van Elsas et al., 2008a, 2008b). Sequencing of a large fosmid library from a grassland soil revealed that a fragment with an rRNA gene, which showed the highest similarity to group 1.1b of the

crenarchaeota, carried genes encoding copper nitrite reductase and two subunits of ammonia monooxygenase or particulate methane monooxygenase (Treusch et al., 2005). The discovery of ammonia-oxidizing Archaea showed the potential of soil metagenomics studies to elucidate the role of uncultured organisms in, for example, soil nutrient cycles (Leininger et al., 2006). Considering that the majority of soil bacteria occur at relatively low abundance but might have an important ecological role, the development of approaches such as targeted access to low-abundance bacteria are of considerable interest. Recently, Hjort et al. (2010) analyzed chitinase genes in DNA directly extracted from a phytopathogen-suppressive soil, in a metagenomic library constructed from microbial cells extracted from soil, and in genomic DNA from bacterial isolates with antifungal and chitinase activities. Although T-RFLP of chitinase genes revealed differences in amplified chitinase genes from the metagenomic library and the directly extracted DNA, approximately 40% of the identified chitinase T-RFs were found in both sources. All of the chitinase T-RFs from the isolates were matched to T-RFs in the directly extracted DNA and the metagenomic library. The authors demonstrated an impressive agreement between three very different screening techniques all of which pointed toward specific *Streptomyces* species that could play a role in suppression of fungi by chitinase production in soil. However, some clusters of chitinase genes were represented depending on the approach used. Therefore, Hjort et al. (2010) concluded that a combination of molecular approaches increases the information obtained and the reliability of the data.

28.1.4 Cultivation-Independent Detection of Genes Carried by Mobile Genetic Elements

The importance of horizontal gene exchange for short-term bacterial adaptability and for successful colonization of new ecological niches has only recently been appreciated (Heuer et al., 2008). Nowadays, mobile genetic elements (MGEs) are recognized as an important and essential component that promotes bacterial diversity. The PCR-based detection of MGE-specific sequences in community DNA was first used by Götz et al. (1996). Primers targeting replicon-specific sequences were designed on the basis of sequenced broad-host range plasmids or integrons. In combination with Southern blot hybridization, a specific and sensitive monitoring of large numbers of environmental samples became possible (Smalla et al., 2000, 2006; Heuer et al., 2002, 2009). While the targeted detection of MGE by endpoint or real-time PCR requires sequence information, capturing MGE directly from soil microbial pellets and subsequent sequencing allow a nontargeted discovery and detection of genes. Direct capturing of MGE by means of so-called exogenous plasmid isolation techniques (Bale et al., 1988; Hill et al., 1992) that have been widely used to capture MGE conferring selectable traits such as mercury or antibiotic resistance have been carried out in a wide range of soils or sediments in Gram-negative recipients functioning as a genetic sink (Heuer et al.,

2002, 2009; Smalla et al., 2006; Binh et al., 2008). Capturing of degradative genes resident on MGE has been demonstrated as well (Top et al., 1995). Increased transfer frequencies have often been observed when the soil environmental sample was previously exposed to pollutants. The PCR-based detection of MGE has been used for monitoring their abundance in soils (Götz et al., 1996; Smalla et al., 2000; Heuer et al., 2009), and "hot spots" with high abundance of MGE could be identified.

28.1.5 Conclusion and Outlook

The tools for cultivation-independent detection of genes in soil bacteria rapidly advanced over the last few years. The technological developments briefly described in this chapter brought us the opportunity to study the enormous complexity of soil microbial communities in more comprehensive and complete terms. The use of molecular tools has dramatically changed our view of the microbes residing in soil. Most importantly, it became possible not only to study who is there but also—although still a methodological challenge—what they are doing. The advances of soil metagenomic tools will continue to improve our understanding of soil microbes. To better understand the enormous microbial diversity and the biotic and abiotic factors shaping their composition and functions, it is certainly needed to study the soil microbiota at different scales and also to develop approaches to target the uncommon or rare populations in soil. The rapidly advancing tools will assist to successfully uncover more secrets of microbial life in soil.

28.2 Expression of Genes in Soil

Giacomo Pietramellara

Judith Ascher

Jiri Jirout

Maria Teresa Ceccherini

28.2.1 Introduction

The detection and monitoring of bacterial gene expression in the environment is important in microbial ecology. The use of molecular techniques for quantifying gene expression by transcriptomic and proteomic analysis in complex soil samples can improve the understanding of the role of many soil microbial species including uncultivable microorganisms, which are the majority of microorganisms inhabiting soil (Torsvik et al., 1996).

The progressive cost reduction of some of these techniques has markedly contributed to the widespread use of molecular tools for analyzing gene expression in soil samples. Among these techniques for the analysis of gene expression of both prokaryotic and eukaryotic cells, there are reverse transcription polymerase chain reaction (RT-PCR), northern and western blotting, RNase protection assays (RPAs), stable-isotope probing (SIP), microarrays, and sequencing methods. The consideration of the advantages and drawbacks of these, as well as the emerging molecular techniques, will be important to evaluate the accuracy and the representativity of the obtained data.

A relevant aspect to consider, that is out of the scope of this chapter, is the opportunity of contemporary analysis of DNA and RNA coextracted from soil in order to have a complete characterization of the soil microbial community, permitting also the assessment of active populations of the soil microbial community and its correlation to specific soil functions.

The aim of this chapter is to give a concise review of the main methods used to study gene expression in soil, including those not yet applied to soil but potentially promising, and to discuss the main factors affecting gene expression in soil.

Some of the techniques discussed in this chapter are also discussed in the specific chapter on gene detection of this section, because they can be used both for evaluating the presence and expression of genes. We think that this overlapping is important for a complete overview of methods for detecting presence and expression of genes.

28.2.2 Gene Expression

28.2.2.1 Definition and Relative Processes

The gene itself is typically a long stretch of DNA and does not perform an active role but is a blueprint for the production of RNA. The process called transcription is performed by RNA polymerases, which add one nucleotide to a growing RNA strand. This RNA is complementary to the DNA nucleotide being transcribed, and mRNA is the information carrier coding for the synthesis of one (common in eukaryotes) or more (common in prokaryotes) proteins. In addition to transcription, gene expression includes RNA splicing, translation, and posttranslational modification of a protein (Kirschner, 1999; Graves and Haystead, 2002). Many factors such as the metabolic state of the cell, the local environment, and chemical signals from other cells affect gene expression. Therefore, an expression profile allows one to deduce the state of a cell in its environment. Gene regulation controls timing, location, and rate of gene expression, determining the versatility and adaptability of any organism.

The aim of transcriptomics is to determine the number of expressed genes through the mRNAs detection.

Consequential to gene expression is the metabolome that represents the collection of all the molecules, which are the end products of gene expression. Metabolomics is the systematic study of the unique chemical fingerprints that specific cellular processes leave behind. Metabolomics, indeed, is the quantitative measure of the phenotype of a biological system and with many other "-omics" sciences represents a key aspect of "system biology."

The main metabolomic molecules studied are proteins. The information carried by proteins is represented by its structures (primary, secondary, tertiary, and quaternary), physical size, and electric charge properties that markedly influence the function of the protein. Thus, the characterization of the proteome by proteomics can be based on expression, functionality, and structure of proteins. The expression permits the quantitative study of proteins in relation to changes in biological or environmental parameters (*expression proteomics*). The functionality can identify specific proteins, their role in individual metabolic activities, and their contribution to the metabolic network operating in the system (*functional proteomics*; Hsieh and Chen, 2008). The third approach permits to characterize the structure of proteins affecting their function (*structural proteomics*; Norin and Sundström, 2002).

28.2.2.2 Gene Expression in Soil

Soil is an extremely complex environment in terms of biochemical activities and contains highly diverse and complex microbial communities (Pietramellara et al., 2002, Graeme et al., 2003). For these reasons, to monitor gene expression of the whole soil microbial community, both RNA and proteins should be extracted in sufficient amounts to be representative of the overall microbial activity of soil (Ogram et al., 1995). Moreover, mRNAs show higher instability and represent a small fraction (~1%–5%) of the total cellular RNA (Neidhardt and Umbarger, 1996). Furthermore, the molecular resolution of soil proteins for elucidating species diversity, functions, and level of activity is extremely difficult due to the large number of different proteins present in soil, and also because one gene can codify the synthesis of several proteins. It is relevant to note that a high percentage of soil proteins, approximately 30%–45% of the soil total N, is present as extracellular proteins (Stevenson, 1986), while intracellular proteins only represent, on average, 4% (Nannipieri, 2006). However, characterization of intracellular proteins should give insights into microbial gene expression in soil. Nannipieri (2006)

named this proteomic approach *functional soil proteomics*, whereas the characterization of extracellular proteins stabilized by soil colloids was named *structural soil proteomics*. The latter characterization could give insights into past biological events.

As for soil DNA extraction, both RNA and proteins can be extracted directly from soil or indirectly after separation of microorganisms from soil (Bakken and Frostegård, 2006; Nannipieri, 2006). It is reasonable to hypothesize that the indirect extraction gives high-quality RNA and proteins but the efficiency is much lower than that of the direct extraction (Nannipieri and Paul, 2009). However, the direct extraction presents some problems because both RNA and proteins can be adsorbed by soil colloids and/or degraded by soil microflora (Norde, 2008). Indeed, soil humic substances and clay particles can bind RNA and proteins interfering with their extraction and purification procedures (Ogram et al., 1995; Trevors and van Elsas, 1995; Trevors, 1996; Griffiths et al., 2000; England et al., 2001; Hurt et al., 2001; Sayler et al., 2001; Sessitsch et al., 2002; Bürgmann et al., 2003; England and Trevors, 2003). Enzyme inhibitors in soil can also inhibit culture-independent analyses (Mendum et al., 1998). Furthermore, high temperatures, extreme pH values, and ionic strength can decrease both RNA and protein extraction efficiency and affect the structural integrity of the protein compromising its information content (Saleh-Lakha et al., 2005). Concerning the pH effect on RNA extraction from soil both Mettel et al. (2010) and Wang et al. (2009) suggest the utilization of low pH lysisi buffer (pH 5.0) and organic solvent (pH 4.5) to minimized the humic acids coextraction with any reduction in the RNA recovery.

28.2.3 Methods for Studying Gene Expression in Soil by Transcriptomic Analysis

Methods for studying gene expression can be divided into (1) culture-independent approaches such as DNA microarrays, northern blotting, fluorescent in situ hybridization (FISH; Parker and Barnes, 1999), ribonuclease protection assay (RPA; Hod, 1992; Saccomanno et al., 1992), RT-PCR (Weis and Reinberg, 1992) coupled with real-time PCR and competitive RT-PCR, or (2) culture-dependent approaches such as SIP (see the specific chapter of this book and Section 28.2.3.3), serial analysis of gene expression (SAGE), and reporter genes. Except for FISH and reporter gene techniques, the other techniques require the extraction of mRNA from samples. The problem of the RNA degradation by RNases, eventually present as contaminants in glassware and reagents, can be avoided by sterilization of glassware and by RNase inhibitors such as DEPC (diethylpyrocarbonate) prior to the extraction procedures (Trayhurn, 1996).

28.2.3.1 mRNA Extraction

28.2.3.1.1 Direct Extraction of Total RNA and mRNA from Soil

RNA isolation protocols by direct extraction include cell lysis, inactivation of RNase activity to prevent losses of RNA, and purification of the extracted RNA with removal of organic contaminants that can be coextracted with nucleic acids (Ogram et al., 1995). Cell lysis for the RNA extraction from soil

can be mechanical (ballistic disintegration of cells using glass or zirconium beads), chemical (solubilization of cell membranes by detergents), enzymatic (digestion of the cell wall membranes), or physical (boiling and freeze–thawing cycles) (Ogram et al., 1995; Borneman and Triplett, 1997; Hurt et al., 2001; Bürgmann et al., 2003). The appropriate extraction technique depends on the soil properties (Borneman and Triplett, 1997). A key step in the RNA extraction procedure is the mRNA separation from total RNA. Subtractive hybridization Ribosomal RNA (rRNA) was utilized by Gilbert et al. (2008) to enhance the mRNA enrichment capturing rRNA from total RNA solution by hybridization on magnetic beads coated with selective probes. It is relevant to note that this approach failed to completely remove rRNA due to insufficient compatibility of the capture probes (Mettel et al. 2010) and also due to not fully substraction of damaged rRNA molecule from total RNA (Gilbert et al. 2008). Frias-Lopez et al. (2008) operated a selective RNA enzymatic digestion in order to obtain an mRNA enrichment through a processive 5′-3′ exonuclease treatment. The enzymes utilized in the rRNA digestion were able to discriminate between the rRNA monophosphate 5′-end and mRNA tri-phosphate 5′-end, that characterize most archeal and bacterial mRNAs, degrading the former RNA (Mettel et al. 2010). Relevant to note that more than 30% of mRNA are present as monophosphate 5′-end in consequence of molecular decay after transcription processes (Celesnik et al. 2007). Cosequently the molecular analysis of exonuclease enriched mRNA result mainly direct to unprocessed mRNA fractions, that are triphosphorylated (Mettel et el. 2010). McGrath et al. (2008) developed a simple method to isolate mRNA from total RNA by size separation using gel electrophoresis, and this method yielded a high number of unique transcripts directly extracted from soil.

28.2.3.1.2 Indirect Extraction of Total RNA and mRNA from Soil

The indirect extraction method is based on previous extraction of microbial cells from soil providing an opportunity to examine the physiological state of extracted cells and to identify individual genes. This extraction requires physical or chemical dispersion of soil followed by a separation of microbial cells from soil particles. The main physical technique used to separate microbial cells from soil particles are shaking, blending, stomacher, and ultrasonication, whereas the chemical techniques include the use of ion-exchange resins, which can reduce the electrostatic attraction between cells and soil particles. To separate cells from soil particles, *buoyant density* can be also used, with the assumption that most cells are not aggregated and can be detached from soil particles. This method is based on ultracentrifugation and the most commonly used density material is Nycodenz (Bakken and Lindahl, 1995; Unge et al., 1999; Berry et al., 2003). Another cell–soil separation technique is the immunomagnetic capture based on the capture of microbial cells by microscopic magnetic beads coated with monoclonal or polyclonal antibodies (Morgan et al., 1991; Fluit et al., 1993; Porter et al., 1998).

It is important to underline that the yield and quality of extracted cells depend on the choice of the most suitable method according to the soil characteristics.

28.2.3.2 Reverse Transcription Polymerase Chain Reaction Technologies

Reverse transcription polymerase chain reaction permits the detection of low amounts of RNA and is easy to be performed with small reaction volumes; the total isolated RNA is subjected to reverse transcriptase to produce complementary DNA (cDNA) copies that are used as templates in a PCR with probes designed to amplify the target gene(s).

28.2.3.2.1 Competitive Reverse Transcription PCR

The competitive reverse transcription polymerase chain reaction (cRT-PCR) permits to quantify the expression of specific genes (McGrath et al., 2000). The technique is based on the competitive coamplification in the same reaction tube of a known amount of an internal standard (competitor) with a sequence of interest and a known amount of the total RNA extracted from the sample. The internal standard has the same primer-binding sites as the target sequence but is usually modified by a small deletion, insertion, or mutation to distinguish it by electrophoresis (Zimmerman and Mannhalter, 1996). Quantification is accomplished by the intensity of the PCR signal of the internal standard; as the amount of internal standard increases, the signal of the target sequence decreases (McGrath et al., 2000; Sharkey et al., 2004). In cRT-PCR, internal standard and target sequences are amplified with equal efficiency, and consequently, their products accumulate with the same kinetics, even if the PCR reagents are present in limiting concentrations.

28.2.3.2.2 Quantitative PCR

Quantitative PCR (qPCR) can be done either by measuring the amount of PCR products at a given number of cycles (endpoint qPCR; Gertsch et al., 2002; Spackman and Suarez, 2008; Udvardi et al., 2008; Van Guilder et al., 2008) or by measuring the amount of products during several PCR cycles (real-time qPCR; Nailis et al., 2006; Logan et al., 2009). These two techniques have been reviewed by Lantz et al. (1999). Here, we only discuss the real-time qPCR as the most utilized quantitative PCR technique.

The real-time qPCR monitors DNA amplification during each PCR cycle through the use of the fluorescence, whose intensity is directly related to the amount of amplicons at the end of each PCR cycle. Therefore, qPCR overcomes the shortcomings of conventional PCR, allowing the quantification of the initial number of gene copies present in the sample, even at a concentration of one genome copy per microliter of soil DNA extract (Gruntzig et al., 2001; Lerat et al., 2005).

28.2.3.2.3 Reverse Transcription PCR/PCR Suppression Subtractive Hybridization

Suppression subtractive hybridization (SSH) permits to detect the influence of environmental variables on gene expression in selected bacteria. This technique is based on the selective hybridization of cDNA, obtained from different environmental samples, with mRNA extracted from a reference sample. Successively, double-stranded cDNA–mRNA hybrids are selectively removed

and the composition of single-stranded cDNA (cDNAss) in the supernatant is analyzed (Utt et al., 1995; Rebrikov, 2003).

28.2.3.2.4 Arbitrarily Primed PCR

Several strategies have been developed for the analysis of small samples in which the amount of available RNA is insufficient for massive gene expression studies (Trenkle et al., 1998; Welford et al., 1998; Sakai et al., 2000; Vernon et al., 2000). A very promising technique is the *RNA arbitrarily primed PCR* (RAP-PCR) method based on the use of nonstoichiometric reduced complexity probes for hybridization to cDNA array membranes (Trenkle et al., 1998). RAP-PCR is an unbiased fingerprinting PCR that samples a reproducible subset of message population based on the best matches with arbitrary primers (Welsh et al., 1992). This technique is capable for the construction of a probe with reduced complexity, which increases the representativity of rare messages starting from small amounts of total RNA or mRNA (Grau et al., 2005).

Aneja et al. (2004) utilized the RAP-PCR technique to investigate the metabolic profiles of the microbial community involved in leaf litter degradation without using selective primer systems. Both mRNA and rRNA transcripts have been successfully targeted in the described protocol, which has the advantage of simultaneous analysis of both active taxa (rRNA) and expression of functional genes (mRNA).

28.2.3.2.5 Rapid Amplification of cDNA Ends

Rapid amplification of cDNA ends (RACE) is a procedure for amplification of nucleic acid sequences from a messenger RNA (mRNA) template located between a defined internal site and unknown sequences at either the 3′ or the 5′ end of the mRNA. This methodology of amplification with single-side specificity has been also described as "one-side" PCR or "anchored" PCR. In general, PCR amplification of a low number of target molecules in a complex mixture requires two sequence-specific primers that flank the region of sequence to be amplified. However, the amplification and characterization of regions of unknown sequences are subjected to severe limitations (Loh et al., 1989), which could be overcome by the 3′- and 5′-RACE methodologies.

The 3′ RACE takes advantage of the natural poly(A) tail in mRNA as a generic priming site for PCR amplification (Park, 2004) whereas 5′ RACE, or "anchored" PCR, is a technique that facilitates the isolation and characterization of 5′ ends from low-copy messages (Schramm et al., 2000).

28.2.3.2.6 Reverse Transcription PCR—Temperature/Denaturing Gradient Gel Electrophoresis

Temperature gradient gel electrophoresis and denaturing gradient gel electrophoresis are molecular fingerprinting methods that separate PCR products of same length based on different sequence compositions resulting in different denaturing characteristics (Muyzer and Smalla, 1998). In the case of soil microbial community studies, these techniques generate banding patterns where each band represents a predominant population of the community. The development of reverse transcriptase PCR (RT-PCR),

transforming RNA in cDNA, empowers the application of T/DGGE techniques to compare the patterns of selected microbial populations (rRNA) with the respective patterns of functional genes through their expression (mRNA–cDNA).

28.2.3.2.7 *The Increase of the RT-PCR Efficiency*

Botero et al. (2005) increased the extraction efficiency of prokaryotic mRNA from environmental samples by coupling poly(A) polymerase with the reverse transcriptase PCR (RT-PCR). Modification of native mRNA molecules with a tail of known oligonucleotide sequences [poly(A)] permits the synthesis of their cDNA. Unexpectedly, no Archaea was detected from poly(A)-modified RNA, whereas additional RT-PCRs performed with universal and Archaea-biased primers and unmodified RNA demonstrated the presence of novel Archaea in the soil. Gao et al. (2007) obtained a sufficient amount of mRNA by reverse transcription with a random hexamer primer with an attached T7 RNA promoter sequence. The synthesized cDNAs were then used as templates for linear RNA amplification with T7 RNA polymerase. Finally, Polidoros et al. (2006) improved inverse-RACE method, which uses CircLigase™ (Epicentre Biotechnologies, Madison, WI) for cDNA circularization, followed by rolling circle amplification (RCA) of the circular cDNA with Φ29 DNA polymerase (New England Biolabs, Ipswich, MA). In this way, a large amount of the PCR template is produced, allowing the simultaneous isolation of the 3′ and 5′ unknown ends of a virtually unlimited number of transcripts after a single reverse transcription reaction. The authors named this method RCA-RACE.

28.2.3.3 Stable-Isotope-Probing Techniques

The application of SIP to nucleic acid studies is among the most promising approaches to link the genetic structure and diversity of autochthonous communities with the physiological status of their representatives or with their own function in situ (Radajewski et al., 2002; Dumont et al., 2006; Bernard et al., 2007; Buckley et al., 2007). The extension of the SIP approach to RNA, which is considered to be a responsive biomarker (Manefield et al., 2002; Lueders et al., 2004), enables the detection of actively metabolizing microorganisms via the expression of the target genes (Radajewski et al., 2003; Ginige et al., 2004; Podar et al., 2007) through the incorporation of stable isotopes' (^{13}C, ^{15}N, ^{32}P, and ^{18}O) rRNA with separation of labeled (heavy) and unlabeled (light) forms by ultracentrifugation in an appropriate density gradient (Radajewski et al., 2003; Schwartz, 2007). The assimilation of the labeled substrate by functional community members can be obtained by adding specific substrates or choosing conditions, under which only certain populations are active (Whiteley et al., 2006). The RNA-SIP method has the potential for wide application in rhizosphere microbial ecology, in particular for tracking carbon flow through different compartments of the rhizosphere microbiota and for assessing the effect of environmental conditions on this flow (Wardle et al., 2004; Lu and Conrad, 2005). The stable ^{13}C-isotope-probing RNA-SIP analysis was capable to highlight an unsuspected diversity of microorganisms living in roots (Vandenkoornhuyse et al., 2007).

The application of combined DNA–RNA-SIP approach showed to be a novel means of linking microbial community function to phylogeny as reported by Bernard et al. (2007) in assessing the dynamics and the diversity of soil bacterial populations actively assimilating ^{13}C derived from labeled plant residues.

A detailed discussion of the use of SIP in the soil–plant system will be present in the specific chapter of this section.

28.2.3.4 Hybridization Techniques

Nucleic acid hybridization techniques are used for the identification of DNA and RNA species with varying degree of homology and for the estimation of relative amounts of nucleic acid with known homology.

28.2.3.4.1 *Northern Blot*

Northern blot involves (1) the use of electrophoresis to separate RNA molecules by size, (2) the transfer of RNA from the electrophoretic gel to the blotting nylon membrane through a capillary or vacuum blotting system, (3) the RNA immobilization on the membrane through covalent linkage promoted by UV light or heat, and (4) the RNA detection with a hybridization probe complementary to a part or to the entire target sequence (Alwine et al., 1977). After hybridization, the membrane is washed to ensure that the probe has bound specifically and to avoid background signals. The hybrid signals are detected by x-ray film and can be quantified by densitometry. The efficiency and the specificity of hybridization can be affected by ionic strength, viscosity, duplex length, mismatched base pairs, and base composition (Engler-Blum et al., 1993). The probes can be labeled either with radioactive isotopes or with chemiluminescence; in this case, alkaline phosphatase (AP) or horseradish peroxidase (HRP) catalyzes the breakdown of chemiluminescent substrates with emission of light (Streit et al., 2008). The northern blot can detect smaller changes in gene expression, and due to its high specificity, it can reduce false-positive results (Engler-Blum et al., 1993).

Concerning soil, Mendum et al. (1998) have tested a quick and reliable technique to extract RNA of a quality suitable for RT-PCR in a fresh sieved clay-rich soil microcosm inoculated with *Rhizobium leguminosarum* CT0370, genetically modified by the insertion in its chromosome of the *uidA* gene codifying for the enzyme L-glucuronidase. The presence of the target transcript, encoding for the L-glucuronidase gene, in the RNA extracted poll was detected by RT-PCR and verified by successive hybridization of the amplified products. This method worked well in the model system; however, the protocol will have to be further optimized to detect the lower levels of mRNA likely to be observed in the field.

Felske et al. (2000) have monitored the composition of predominant soil bacteria during grassland succession at the level of major bacterial taxa coupling multiple competitive RT-PCR with quantitative dot blot hybridization. The dot blot hybridization technique is a simplification of the northern blot, where the mixture containing the target molecule is not firstly separated by gel electrophoresis but directly applied on a membrane as a dot. The monitored predominant ribosome types (16S rRNA)

represented approximately half of all bacterial soil rRNA, which was estimated by dot blot hybridizations of soil rRNA with the bacteria probe EUB338. These ribosome types mainly represented Bacillus and members of the Acidobacterium cluster and the alpha-subclass of Proteobacteria.

28.2.3.4.2 Fluorescent In Situ Hybridization

Fluorescent in situ hybridization permits the detection of a gene of interest through the hybridization of a target gene with a specific fluorescently labeled probe (Bakermans and Madsen, 2002; Ginige et al., 2004) and also the identification of active bacteria within a community or population directly in the environment of interest.

The application of FISH in nutrient-poor environments such as roots and soil is more problematic due to lower cell numbers and the presence of interfering autofluorescence from roots and soil particles. Briones et al. (2002) employed FISH using rRNA-targeted oligonucleotide probes providing, for the first time, population estimates of ammonium oxidizer bacteria (AOB) on the rice root surface. These results were supported by DGGE of the *amoA* gene and analysis of libraries of cloned *amoA*.

A promising application of FISH is its coupling with microautoradiography (MAR) and with stable-isotope probe [MAR–SIP and fluorescent DAPI (4,6-diamino-2-phenyl-indole)] providing information about the bacterial community density, activity, and specific substrate uptake (Ginige et al., 2004).

Compared with other environments, FISH has not frequently been applied in soil and showed quite low detection rates related to total DAPI cell counts (Bouvier and del Giorgio, 2003). It was reported that the detection of FISH-stained cells in soil was mostly affected by autofluorescent soil particles (Hahn et al., 1993; Zarda et al., 1997). This effect could be avoided by the extraction of bacteria with Nycodenz prior to FISH and the use of laser scanning microscopy (Bertaux et al., 2007). Recent applications of FISH in soil were used to analyze shifts in the soil microbial community (Stein et al., 2005) and to visualize microorganisms in undisturbed soil samples (Eickhorst and Tippkötter, 2008a) by its combination with microcalorimetric measurements and micropedological methods, respectively. Eickhorst and Tippkötter (2008b), coupling FISH with catalyzed reporter deposition (CARD), drastically improved the in situ hybridization increasing the fluorescence intensity at the target binding site of the probe by tyramide signal amplification (TSA). As a result, CARD–FISH-stained cells were suitable for automated counting using digital image analysis.

Other FISH-based techniques, like Raman microscopy in combination with FISH and multi-isotope imaging mass spectrometry (MS) (or nano-SIMS), actually in development may permit a marked increase in the detection capacity.

Raman microscopy detects stable-isotope incorporation into cellular constituents, offering a possible advantage over FISH–MAR by obviating the need to handle radioisotopes and facilitating the cumbersome quantification of silver grains. Furthermore and in contrast to FISH–MAR, Raman provides information into which cellular compounds the labeled substrate was incorporated. Recently, FISH and Raman confocal microscopy have been directly combined to confirm the involvement of *Pseudomonas* spp. in the assimilation of $^{13}C_{10}$–naphthalene in groundwater (Huang et al., 2007).

The nano-SIMS technology analyzes the stable- or radioactive-isotope content of single cells at a resolution higher than both Raman microscope and MAR (Kuypers and Jørgensen, 2007). As already achieved for Raman–FISH, a combination of FISH–nano-SIMS would enable phylogenetic and isotopic analysis of an environmental sample in a single scan. Furthermore, it might even become possible to couple isotope array experiments, performed after the addition of stable-isotope-labeled substrates, with nano-SIMS. Such combination would provide high throughput, stable-isotope-based analysis of microbial communities, and their functions. Owing to the high spatial resolution of nano-SIMS, these analyses could possibly be performed in a massively parallel manner with high-density arrays (Lechene et al., 2006).

28.2.3.4.3 Flow Cytometry—Fluorescence-Activated Cell Sorting

Flow cytometry—fluorescence-activated cell sorting (FC-FACS) is a powerful method for the detection and quantification of fluorescence from individual cells within a population. FACS provides data on optical properties of thousands of single cells per second as they pass through a laser beam (Nebe-von-Caron et al., 2000).

The FC-FACS method for in situ analysis and quantification of gene expression at a single-cell level opens up new possibilities for coherent studies of activity and diversity of the soil microbial community.

De Werra et al. (2008) demonstrated the capability and efficiency of a novel FACS-based method to quantify the expression of antifungal genes in *Pseudomonas fluorescens* CHA0 colonizing plant roots.

28.2.3.4.4 RNase Protection Assay

RNase protection assay permits the detection and quantification of specific mRNA transcripts in a complex mixture of total RNA or mRNA molecules (Müller et al., 2001). The RNA probe, complementary to the gene sequence of interest, with incorporated radioactive ($CT^{32}P$) or biotinylated nucleotides (Biotin-N^4-CTP), is synthesized through an in vitro transcription reaction. This labeled probe is incubated with a sample of total RNA or mRNA to facilitate the hybridization reaction. The hybridization mixture is then treated with ribonuclease (RNase) to eliminate not hybridized single-stranded RNA molecules. Usually, the sample is electrophoresed on a denaturing Tris–borate–EDTA (TBE)–urea polyacrylamide gel and detected by methods specific for radiolabeled or biotinylated probes. With respect to the former, the latter probes can be used without gel purification and are more stable (years vs. weeks). Müller et al. (2001) proposed multiprobe RPA sets that are valuable tools for the simultaneous quantitative determination of gene expression.

28.2.3.4.5 Microarrays

DNA microarrays have been used for bacterial detection and to monitor the physiological status and functional activities of microbial community (Ball and Trevors, 2002; Dubois et al.,

2004). In microarrays, the probes, oligonucleotide, cDNA, or small fragments of PCR products that correspond to mRNAs are synthesized prior to deposition on the array surface and then "spotted" onto glass. The resulting "grid" of probes represents the nucleic acid profiles of the prepared probes and is ready to receive complementary cDNA or RNA "targets" derived from experimental samples. By hybridizing cDNA with different fluorophores, the detection of different target cDNAs is possible (Shalon et al., 1996).

The whole-genome microarrays, through target bacteria transcriptional profiles, permit to reveal the extent and complexity of the wild-type *Agrobacterium tumefaciens* adaptation and responses to plant signaling under soil acidic condition identifying several acid-inducible genes, which may be directly involved in agrobacterium–plant interactions (Yuan et al., 2008).

Tiling arrays are a subtype of microarrays frequently utilized to find expressed genes, characterized by the utilization of overlapping probes in very close proximity to obtain an unbiased analysis with higher resolution, permitting the detection of small and rare molecules. Different degrees of resolution depend on the lengths and spacing of the utilized probes.

28.2.3.4.6 *Selective Capture of Transcribed Sequences*

Selective capture of transcribed sequences (SCOTS) permit the direct identification of specifically expressed genes of any microorganism from which genomic DNA can be obtained, without the need of specialized genetic techniques (e.g., DNA microarrays, libraries, species-specific cloning vectors). SCOTS allows the selective capture of bacterial cDNAs from total cDNA using hybridization to specific biotinylated bacterial genomic DNA (Graham and Clark-Curtiss, 1999).

28.2.3.5 Sequencing Technologies

To sequence transcriptomes, various methods have been developed to directly determine cDNA sequences based mostly on traditional (and more expensive) Sanger's sequencing, while others include methodologies such as SAGE and RNA-sequencing (RNA-seq).

28.2.3.5.1 *Serial Analysis of Gene Expression*

Serial analysis of gene expression produces a snapshot of the mRNA population in a sample of interest in the form of small tags that correspond to fragments of those transcripts. The tagged mRNAs are converted to cDNA by RT-PCR and then ligated together into concatemers, after linkers digestion with the appropriate restriction enzymes. Successively to concatemerization, the fragments are ligated into plasmids and are used to transform bacteria; the growth of the transformed bacterial population generates many copies of the plasmid containing the inserts. Those may be sequenced to identify the present mRNA, as well as analyzing expression levels of a given mRNA by counting the present number of copies (Velculescu et al., 1995).

28.2.3.5.2 *RNA-Sequencing*

RNA-sequencing is a revolutionary tool for transcriptomics (Subramanian et al., 2005) based on the use of high-throughput sequencing technologies used to sequence cDNA.

RNA-sequencing can be done with a variety of platforms but here we briefly illustrate only the pyrosequencing 454 technique due to its wide diffusion, and the most promising new techologies, such as Pacific Biosciences, Ion Torrent and Oxford Nanopore.

In pyrosequencing, the cDNAss molecule fragments (max 500 bp) are physically bound to a surface and sequenced in parallel using DNA polymerase and adding one nucleotide species at a time. The number of nucleotides incorporated by the synthesis is quantified by light emitted by the released pyrophosphates. Advantages of the pyrosequencing 454 technique mainly consist in a significant reduction of time and cost of the metagenome approach, permitting to sequence genomes without its isolation by cloning (Marsh, 2007).

Parallel tagged sequencing (PTS) is a molecular barcoding method designed to adapt the recently developed high-throughput 454 parallel sequencing technology to multiple samples (Meyer et al., 2007). The next generation sequencing technology are represented by Pacific Bioscience, Ion Torrent and Oxford Nanopores that darstically decreasing the DNA detection threshold. The Pacific Bioscience maintain the utilization of the fluorescence probes to detect the nucleotides added during the DNA sequencing, wherease the latter two are defined as post-light sequencing technology detecting the nucleotides on the characteristic variation induced on pH values and ionic current flow of the solution, respectively. These latter two techologies should permit a drastic reduction of sequencing machine and reaction costs, increasing also the sequencing speed (Clarke et al. 2009; Metzker 2010; Pennisi 2010).

After cDNA sequencing, the sequence must be aligned. Sequence alignment consists in arranging cDNA to identify regions of similarity. The main alignment methods are based on computational algorithm approaches and could be classified as *global alignment*, where the alignment spans the entire length of all query sequences; *local alignment*, which identifies regions of similarity within long sequences that are overall often widely divergent; and *hybrid methods*, a combination of the global and local alignment methods.

28.2.3.5.3 *Signature-Tagged Mutagenesis*

Recent advances in genome sequencing have permitted to catalog genomes of a large variety of organisms, but the function of their genes is still largely unknown. Signature-tagged mutagenesis (STM) permits to infer what function the product of a particular gene has by disabling it and observing the effect on the organism. The original and most common use of STM is to discover the genes in a pathogen, which are involved in virulence in its host, so that better curative treatments can be designed (Saenz and Dehio, 2005).

28.2.3.6 Bioreporter and Related Reporter Genes

Reporter genes provide a mean of studying and quantifying gene activity in situ (Sayler et al., 2001). Reporter genes are usually fused to the gene of interest for which the activity needs to be quantified. There are various types of reporter genes available, and their selection depends on the sensitivity of the promoter and the type of detection with which the reporter gene can be quantified (Köhler et al., 2000). They can generate colorimetric, fluorescent, luminescent, chemiluminescent, or electrochemical signals, which have the common characteristic to be easily measurable

and proportional to the rate at which the gene is expressed and to the concentration of the inducing substrate. Environmental factors (temperature, pH, moisture, initial substrate concentrations, etc.) can influence the relationship between expression of the gene of interest and luminescence response of the reporter gene (bioluminescence); these factors can significantly affect the quantification of gene expression (Dorn et al., 2003).

The following section briefly outlines some of the available reporter gene systems and their applications.

28.2.3.6.1 Luciferase

Luciferase (*Lux*) is a generic name for an enzyme, found in prokaryota and eukaryota, that catalyzes a light-emitting reaction (bioluminescence). Three variants of *Lux* are available, whose activity differs for the optimal temperature (<30°C, <37°C, and <45°C). Jensen et al. (1998) hypothesized that the luciferase enzyme was stable in bacterial cells inhabiting soil, and subsequently, this could be a limitation to the use of the *luxAB* system as a monitoring tool of the gene of interest. Another limitation to the use of the *Lux* genetic system for studies of soil microbial populations is its energetic demand on cell metabolism.

28.2.3.6.2 Green Fluorescent Protein

Advantages of the green fluorescent protein (GFP) are its easy expression and detection in both prokaryotic and eukaryotic organisms; its use at the single-cell level does not require exogenous substrates or cofactors and requires a lower energetic demand than luminescent markers. Further advantages are its sensitivity, high stability, and resistance to denaturants. Additionally, the ability to alter GFP to produce light emissions besides blue (i.e., cyan, red, and yellow) can allow the use of this technique as a multianalyte detector. Disadvantages include expression variability, lower sensitivity than *luxB* gene, the request of oxygen, the unknown influence of environmental conditions, and the background interference by other fluorescent particles or bacteria (Errampalli et al., 1999; Kohlmeier et al., 2007).

28.2.3.6.3 β-Galactosidase (lacZ Gene)

The *lacZ* gene of *Escherichia coli* encodes the enzyme β-galactosidase, capable of cleaving lactose into glucose and galactose and also the synthetic compound X-gal (5-bromo-4-chloro-3-indolyl-b-d-galactoside) producing a blue pigment (Jensen et al., 1998; Koch et al., 2001; Dorn et al., 2003). The advantages of *lacZ* reporter genes are their efficiency in both prokaryotic and eukaryotic cells, their high turnover rate, their strong signals with different substrates, and the high detection sensitivity of the relative technique (Köhler et al., 2000). The main limitation of this reporter gene is the background level of endogenous β-galactosidase activity within cells, which vary greatly (Lewis et al., 1998), and the need to culture the microorganisms on X-gal medium to detect the expression of the β-galactosidase enzyme.

28.2.3.6.4 Bioreporter Functioning

To be active, the reporter gene needs to be inserted in a host organism, the so-called bioreporter, which is a living cell that has been genetically engineered to produce a measurable signal in response to a specific chemical or physical agent in their environment. Concerning soil, the bioreporter has to be representative of soil-inhabiting microorganisms or to be a specific microorganism for a specific purpose when the strain is constructed. *Pseudomonads* are generally the preferred microorganisms due to their abundance in soil environments (Jensen et al., 1998). Originally developed for fundamental analysis of factors affecting gene expression, bioreporters have been used for the detection of environmental contaminants (Brueckner et al., 2009) and have evolved in fields such as precision agriculture and food safety assurance. Their versatility is due to the high number of reporter gene systems capable to generate a variety of signals (vectors).

To assemble a bioreporter, the promoter gene-trapping technique (PGT) is very efficient. This approach involves the introduction of a promoter gene fused with a reporter gene into the genome, which leads to the isolation and activity detection of the trapped gene of interest (Liu et al., 2006).

Among the PGT are those based on in vitro and in vivo expression technology (IVET) and on differential fluorescence induction (DFI).

The in vitro IVET is an approach to identify gene products that are turned off in one environment (e.g., in laboratory media) but turned on in a different environment (e.g., during infection of a host). This technique has been utilized to establish the genetic determinants important for the life style of target organisms (Ramos-Gonzales et al., 2005).

The PGT techniques based on in vivo IVET and on DFI are mainly utilized to identify and study genes of interest with elevated levels of expression in complex environments. This capacity permits to explore niche-specific gene expression, like identification of genes involved in microbe–plant interactions (Silby and Levy, 2004; Ramos-Gonzales et al., 2005) and also provide useful information about how an organism perceives its environment.

Several variations on the original IVET have emerged, based on different selection strategies such as recombinase selection and system-specific selection. The former is defined as recombinase-based in vivo expression technology (RIVET), founded on the activation of a site-specific DNA resolvase that permits to isolate transiently or weakly expressed genes in a selected environment. The latter one permits to identify genes (promoters) differentially expressed during particular stage of the interaction between a bacterium and its eukaryotic host.

Complementary strategies to PGT-IVET/DFI are signature tagged mutagenesis (STM) (Hensel et al., 1995; Saenz and Dehio, 2005), differential display using arbitrarily primed PCR (McClelland et al., 1995; Fislage, 1998), suppression subtractive hybridization (SSH) (Ito and Sakaki, 1996, 1997), and selective capture of transcribed sequences (SCOTS) (Graham and Clark-Curtiss, 1999).

28.2.3.7 Main Advantages and Disadvantages of the Reported Methods for Gene Expression Studies by Transcriptomic Analysis

Reverse transcription PCR is the most sensitive and flexible of the quantification methods (Wang and Brown, 1999), and it permits to avoid cloning steps and generate reagents, such as full-length

cDNA inserts for cloning (Borson et al., 1992), or arbitrarily primed enhanced sequence tag cDNA libraries (Neto et al., 1997).

Suppression subtractive hybridization is characterized by a simple and efficient strategy to obtain rare cDNAs by the selective digestion of dominant double-stranded cDNA–mRNA hybrids, followed by successive amplification of not annealed fragments, which will grow faster becoming dominant (Rebrikov, 2003).

RNA arbitrarily primed PCR is useful if no prior knowledge is available about functional genes of the microbial community to be analyzed and also permits to increase the array techniques efficiency by reducing the probe complexity and increasing the number of screened differentially expressed genes (10 times higher) respect to those detectable with total cDNA probes (Trenkle et al., 1998; Sakai et al., 2000).

The main drawback of RACE-PCR is the difficulty to bind the unknown RNA fragment to the terminal end of known RNA/cDNAss fragments. Recently, an innovative RACE-PCR based on the utilization of bacteriophage T4 ligase has been proposed (German et al., 2008). Bacteriophage T4 ligase covalently attaches the unknown RNA fragment to the 5′ terminal end of a known mRNA, increasing the efficiency of the successive RT-PCR.

RT-PCR-D/TGGE advantages include simple performance, high sensibility, and reproducibility, whereas the main disadvantage is the PCR dependency, with detection of only dominant target genes.

The SIP technique (only) permits detecting cells that are actively replicating in situ during the pulse with the exclusion of the slow-growing microorganisms that outcompete during enrichment (Manefield et al., 2002, 2006; Radajewski et al., 2003). Other limitations of SIP are the time request by microorganisms for the assimilation of the labeled substrate and the possibility of cross-feeding because labeled products and intermediates of the substrate metabolism can be taken up by nontarget microorganisms (Radajewski et al., 2000, 2003; Whitby et al., 2001; Morris et al., 2002). A further critical step in applying DNA- or RNA-SIP techniques to environmental samples is the need to physically separate labeled from unlabeled molecules using density gradient centrifugation (Friedrich, 2006). The necessity of adding a ^{13}C-labeled substrate to the environmental sample may cause bias by physical disturbance and a change of in situ substrate concentrations (Lu and Conrad, 2005). An advantage of SIP-RNA respect to SIP-DNA is based on fact that RNA synthesis is rapid and its labeling can occur without the need of DNA synthesis or replication of the organism (Manefield et al., 2002; Radajewski et al., 2003).

Concerning the hybridization techniques, the advantages of using northern blotting include the opportunity to verify quality (size) and quantity of RNA on the gel prior to blotting, the use of probes with partial homology, and the storage and reprobing of the membranes for years after blotting (Streit et al., 2008). In the case of RPA, the hybridization of the probe and target mRNA is made directly in solution to maximize the target availability and thus permits detecting rare messages, discriminating between related mRNAs of similar size, which migrate at similar positions on a northern blot, and probing multiple transcripts in one RNA sample. The main limit of the RPA efficiency is the size

of the probes due to the destruction of the nonhybridized RNA during the nuclease digestion step.

With respect to other hybridization methods, microarrays permit visualizing thousands of genes at a time. In comparison, RT-PCR northern blotting has a low sensitivity but it is characterized by a high specificity, which is important to reduce false-positive results (Streit et al., 2008). A disadvantage of microarrays is the lack of standardization in platform fabrication, assay protocols, and analytical methods that makes microarray data difficult to be interpreted, also due to their huge number (especially for tiling array).

The SCOTS technique, unlike other methods for analysis of in vivo gene expression (e.g., IVET, DFI, and STM), permits to identify potentially important genes rather than promoter regions and is not confounded by polar effects when genes are arranged in prokaryotic polycistronic operons. This method overcomes the problems related to very small numbers of target microorganisms, instability of bacterial mRNA, and difficulties involved in separating bacterial mRNA from ribosomal RNA (rRNA) and host RNA. SCOTS is suggested to introduce only a limited bias in gene expression analysis (Graham and Clark-Curtiss, 1999).

The in situ hybridization and SIP techniques are the most complex assays, but they are the only ones capable of localizing transcripts in living cells.

The application of FISH to soil is still problematic for the aspecific effects of soil particles (Nannipieri et al., 2003). The main limit of the FISH method applied to soil studies is due to the autofluorescence of soil particles and the small size of soil bacteria, which can be shown only by *dim fluorescence* (Hahn et al., 1992; Christensen et al., 1999). The problems related to the use of FISH and FISH–MAR in soils and sediments have been discussed by Rogers et al. (2007).

FC-FACS permits to quantify both the bacterial gene expression in soil populations at a single-cell level and the size of a bacterial population without using traditional culture-dependent methods such as plating serial dilutions on selective agar. A consistent problem with the use of flow cytometry in environmental applications is the background noise originating from basal autofluorescence of bacteria or from soil, plant, substrate, and other contaminating particles emitting fluorescence that may interfere with analysis of relevant data (Nebe-von-Caron et al., 2000; De Werra et al., 2008).

Regarding sequencing technologies, SAGE is able to quantify gene expression through a direct count of the number of transcripts. In addition, as the mRNA sequences do not need to be known a priori, unknown genes or gene variants can be discovered. At present, major limitations of SAGE are the high cost and that the gene assignment is limited on the identified cDNA sequences (database) (Lash et al., 2000; Boheler and Stern, 2003; Pleasance et al., 2003).

High-throughput sequencing technologies (454 sequencing), parallelizing the sequencing process, can produce thousands or millions of sequences at once, reducing the cost of DNA sequencing with respect to standard dye-terminator sequencing methods.

The principal characteristics of bioreporter and related reporter genes are the capacity of generating measurable signals

that are proportional to the concentration of the target chemical or physical agent to which are exposed (Brueckner et al., 2009). The main advantages of this technique are to not utilize microbial mRNA, to not require extensive knowledge of the genome of the target microorganisms, and to permit the detection of differences in gene expression occurring within a population inhabiting different environments (e.g., biofilm, rhizosphere, animal host). The main drawbacks of the method are to be unable to isolate repressed promoters, to detect genes that are regulated posttranscriptionally and proteins constitutively expressed but only activated in the wild. Another disadvantage, especially in soil, is represented by the sensitivity of bioreporters to target substrate concentration and availability. Concerning the type of the reporter gene, it has also to be considered that the signal can occur only in the presence of a secondary substrate, which has to be added to the bioassay (*luxAB*, *Luc*, and aequorin), or cannot be self-induced, like *luxCDABE* reporter genes, requiring an external light source (GFP and UMT). Finally, the reporter gene host has to be a representative environmental organism or a specific organism for a specific purpose when it is constructed.

A clear advantage of the IVET technology is that investigations are carried out in the appropriate environment of the target organisms; there is no extrapolation from in vitro model systems. The technique as normally used, however, excludes genes that show significant expression in vitro in minimal medium and identifies only those that are upregulated in the rhizosphere (Silby and Levy, 2004; Ramos-Gonzales et al., 2005).

28.2.4 Gene Expression and Soil Proteomics

28.2.4.1 Protein Extraction Methods

The proteomic approach applied to soil is based on the extraction of proteins from soil. Several extraction protocols for soil proteins have been published (Wright and Upadhyaya, 1996; Rilling et al., 2002; Bolygo et al., 2003; Singleton et al., 2003; Barzaghi et al., 2004; Harner et al., 2004; Ogunseitan and LeBlanc, 2004; Nannipieri, 2006; Ogunseitan, 2006). The extraction strategy varies according to the targeted protein fraction (i.e., prokaryotic/eukaryotic and extracellular/intracellular) and by the subsequent methods of protein analysis (i.e., 2D comparative protein maps or measurement detection of specific polypeptides or enzymatic activities) (Maron et al., 2007). Here, we briefly discuss the indirect soil protein extraction method by Maron et al. (2008) and the direct extraction method by Benndorf et al. (2007). The indirect approach is based on the extraction of microorganisms from soil prior to protein extraction, whereas the direct extraction of soil proteins involves the cell lysis in the soil sample. Both approaches present advantages and disadvantages. The indirect extraction gives purer proteins than the direct extraction but a lower yield and thus a scarce representativity of the proteins codified by soil genes. In addition, proteome can change during the extraction of microorganisms and from soil.

Maron et al. (2008) extracted bacteria from soil suspensions by high-speed centrifugation with a nonionic density gradient created by Nycodenz (Nycomed Pharma, Norway) (Bakken and

Lindahl, 1995). Bacterial cells were lysed by sonication and the protein concentration was determined by the Bradford method (Degens et al., 2000). Colorimetric methods such as the Bradford method have been used to determine the protein concentration of soil extracts in several studies but they can give artifacts as discussed by Nannipieri and Paul (2009).

Benndorf et al. (2007) extracted proteins from soil using a 0.1 M NaOH–phenol solution. The NaOH solution extracts humic acids and proteins from soil minerals by disruption of microbial cells. The subsequent phenol extraction separates the proteins from the humic organic matter. Protein extracts were analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and 2D electrophoresis (2DE). Spots and bands were excised from the 2DE gel, solubilized, and hydrolyzed by trypsin for protein characterization. Tryptic peptides were analyzed by MS and the isolated proteins were assessed by database research.

To increase the protein extraction efficiency, an ultrasonication treatment of soil may be applied; this treatment solubilizes the protein fraction immobilized on soil colloids. To avoid the risk of protein denaturation, it was suggested to work at low temperature (Ogunseitan and LeBlanc, 2004). Furthermore, Renella et al. (2002) have proposed the use of a protease inhibitor cocktail to inhibit proteases during cell lysis. The combination of the autoclave treatment and the protein extraction with buffer has been used to extract glomalin, a glycoprotein produced by soil mycorrhizae (Wright and Upadhyaya, 1996, 1998; Rilling et al., 2002). It has been shown that such extractions give humic-like compounds rather than glycoproteins (Schindel et al., 2007).

28.2.4.2 Protein Characterization after Their Extraction and Purification

The expression level of encoding protein genes can be directly assessed by assays similar to those used for quantifying mRNA.

28.2.4.2.1 Hybridization Techniques

28.2.4.2.1.1 Western Blot   Western blot permits to identify proteins of interest using gel electrophoresis to separate native or denatured proteins by the length of the polypeptide (denaturing conditions) or by the 3D structure of the protein (native/nondenaturing conditions), giving also information about their size. The proteins are then transferred to a membrane, typically nitrocellulose or polyvinylidene fluoride (PVDF), where they are detected using antibodies specific to the target protein (Renart et al., 1979; Towbin et al., 1979). The antibody can either be conjugated to a fluorophore or to HRP for imaging and/or quantification.

28.2.4.2.1.2 Enzyme-Linked Immunosorbent Assay   The enzyme-linked immunosorbent assay (ELISA) uses antibodies immobilized on a microtiter plate to capture proteins of interest from samples added to the well. Using a detection antibody conjugated to an enzyme or fluorophore, the quantity of bound proteins can be accurately measured by fluorimetric or colorimetric detection. ELISA can be performed with several modifications of the basic

procedure. The key step, immobilization of the antigen of interest, can be accomplished by direct adsorption to the assay plate or indirectly via a capture antibody that has been attached to the plate. The antigen is then detected either directly (labeled primary antibody) or indirectly (labeled secondary antibody). The most powerful ELISA assay format is the sandwich assay. The analyte to be measured is bound between two primary antibodies, the capture antibody and the detection antibody. The sandwich format is preferentially used because it is sensitive and robust.

The most commonly used enzyme are HRP and AP. Other enzymes have been used as well (β-galactosidase, acetylcholinesterase, and catalase), but they have not gained widespread acceptance because of limited substrate options. The choice of substrate depends upon the required assay sensitivity and the instrumentation available for signal detection (spectrophotometer, fluorometer, or luminometer).

28.2.4.2.1.3 Protein Microarrays

Three types of protein microarrays are currently used in proteomic research: analytical, functional, and reverse-phase microarrays.

The *analytical protein microarrays* are typically used to characterize a complex mixture of proteins according to their binding affinities, specificities, and expression level (Bertone and Snyder, 2005). The *functional protein microarrays* are based on chips of full-length functional proteins or protein domains and are used to study protein–protein, protein–DNA, protein–RNA, protein–phospholipid, and protein–small molecule interactions (Zhu et al., 2001; Hall et al., 2004). In the reverse-phase protein microarray (RPA), the lysate of isolated cells is arrayed onto a nitrocellulose slide and then probed with antibodies against the target protein of interest. The antibodies are detected by chemiluminescent, fluorescent, or colorimetric assays. Reference peptides are printed on the slides for protein quantification of the sample lysates. This technique discriminates between proteins altered by posttranslational modifications, for example, as a result of disease.

Surface plasmon resonance, carbon nanotubes, carbon nanowires, and microelectromechanical system cantilevers techniques are not yet suitable for the detection of high-throughput protein interactions but they seem to be very promising (Ramachandran et al., 2005).

28.2.4.2.2 Gel Electrophoresis

28.2.4.2.2.1 Two-Dimensional Gel Electrophoresis

Two-dimensional sodium dodecyl sulfate polyacrylamide gel electrophoresis (2D-SDS-PAGE) involves the migration and separation of polypeptides in two dimensions according to their isoelectric point and molecular weight, respectively. Recent advances in 2D gel electrophoresis (2DGE) are represented by difference gel electrophoresis (DIGE) that permits to compare different proteins on the same gel by the contemporary utilization of two different protein fluorescent tags (Unlu et al., 1997). Bands of the electrophoretic patterns can be excised and the relative proteins solubilized and analyzed. Usually after solubilization proteins are hydrolyzed by trypsin and the tryptic peptides are analyzed by MS as discussed before. Another interesting technique is the isotope-coded affinity

tag (ICAT) assay, where proteins are treated with the same chemical reagent differing in the mass values due to the different isotopic composition in the linker region. This technique permits to quantify the level of the protein expression (Graves and Haystead, 2002).

28.2.4.2.3 Mass Spectrometry

MS is based on the ionization of chemical compounds to generate charged molecules or molecule fragments, followed by the measurement of their mass to charge ratios. The type of ionization depends on the sample to be analyzed by MS. In the case of liquid and solid biological samples, two soft laser desorption techniques can be used: the matrix-assisted laser desorption/ionization (MALDI) and the surface-enhanced laser desorption/ionization (SELDI). Both MALDI and SELDI are also used for the fragmentation of proteins and peptides. Usually, proteins are digested by trypsin before MS analysis (Nannipieri and Paul, 2009).

28.2.4.2.4 Two-Dimensional Gel Electrophoresis and Liquid Chromatography Combined with MS and MS/MS

In order to increase our protein identification ability especially in difficult environment, such as soil with the presence of unknown sequences species and complex mixture, it has been proposed to combine the separation power of 2DGE and liquid chromatography (LC) with MS or MS/MS peptide information based on molecular mass (MS) and both molecular mass and fragmentation (MS/MS).

Challenges for the use of 2DGE–MS include limitations in the molecular sizes, pI ranges, and hydrophobicities of the proteins that can be analyzed. Furthermore, even with automated techniques, the ability to identify more than a few hundred proteins from a gel plate containing a thousand spots is still very difficult and generally low throughput (Keller and Hettich, 2009).

Benndorf et al. (2003) used a combination of SDS-PAGE and LC–ESI–MS to analyze proteins extracted from contaminated soil and groundwater. To assess the suitability of this approach for the functional analysis of environmental metaproteomes, it was applied to soil that had been enriched in chlorophenoxy acid-degrading bacteria by incubation with 2,4-dichlorophenoxyacetic acid for 22 days. The identification of enzymes such as chlorocatechol dioxygenases was consistent with bacterial metabolic pathways expected to be expressed in these samples.

28.2.4.2.5 Proteogenomics

The ability of the proteomics approaches integrating online high-performance LC-MS/MS coupled with a computational matching algorithms to compare the experimental fragmentation spectrum with the predicted fragmentation spectrum of the putative peptide sequence suggested by the genome information can be used to verify coding regions of a genomic sequence, to validate predicted genes at the level of translation, to detect novel genes, and also to confirm translation of hypothetical proteins. These opportunities are named proteogenomics (Banfield et al., 2005; Ansong et al., 2008).

Ram et al. (2005) reported the efficiency of LC-MS/MS-based proteomics to metagenomics to evaluate gene expression, identify key activities, and examine partitioning of metabolic functions in a natural acid mine drainage (AMD) microbial biofilm community.

Ansong et al. (2008) have highlighted several ways in which high-throughput tandem MS-based proteomics can improve the quality of genome annotations, with emphasis on microbial genomes, concluding however that further improvements are still needed to make this search routine less problematic and more widely applicable. Gilbert et al. (2008) in their studies on the metatranscriptome of a complex marine microbial communities provides evidence that metagenomic and metatranscriptomic combined approache could, offer an unprecedented opportunity to obtain a functional metabolic profile predicting the expressed proteins by translate the sequence informations in peptides that are compared against know databases.

28.2.4.3 Advantages and Disadvantages of the Methods Used in Proteomic Analysis

As discussed before, proteomic analysis can be done by different methods such as western blot, ELISA, 2DGE, MS, in situ hybridization, and protein microarrays. The advantages and disadvantages of these methods are summarized in the following.

The gel-based nature of the western blot assay makes the quantification less accurate but it has the advantage of being able to identify later modifications (proteolysis or ubiquitination) of the protein due to changes in molecular size.

The ELISA detection process is similar to the western blot, but, since there are no gel steps, a more accurate quantification can be achieved. Although the ELISA *direct* detection involves fewer steps than western blotting, it is expensive and time-consuming due to the need of a specific labeling antibody for each protein with a significant reduction of flexibility. The ELISA *indirect* detection assay can use a wide variety of labeled secondary antibodies (available commercially), leading to higher flexibility and higher detection capacity than the ELISA *direct* detection assay. The occurrence of cross reactivity with secondary antibodies, producing nonspecific signals, and the use of complex protocol represent the main drawbacks.

The 2D-SDS-PAGE is expensive, time-consuming, and has a limited resolution capacity that does not permit the detection of all proteins in a complex mixture, particularly those present in low quantities (Graves and Haystead, 2002).

The MS-based proteomics is widely used in studies of proteome or subproteome of cells, whereas its use in environmental research is rare because of the assumption that free proteins are not sufficiently stable in the environment. MS is expensive; trained technicians are required for its functioning and bioinformatic experts are needed to determine the type of protein (Han et al., 2008).

Protein microarrays are commonly used to contemporarily determine several proteins, while western blotting is usually monitoring a small number of proteins. As reported above, the drawback of microarrays applied to transcriptomic analysis is the lack of standardization of platform fabrication, assay protocols, and analysis methods, making the comparison and interpretation of microarray data difficult; it is an interoperable problem in bioinformatics. However, constructing a proteome microarray not only allows an overexpression library, but also provides a high-throughput expression and purification protocol producing thousands of pure and functional proteins that can be utilized in microarray analysis (Hall et al., 2007).

Concerning proteogenomics, which should permit to identify both the gene and its complement proteins from the dominant organisms, there are technical obstacles currently restricting this type of approach to soil. The main drawback is the low DNA/protein extraction efficiency that do not permit to capture the full range of genetic potential of the soil microbial communities. Furthermore, many of the identified proteins have unknown function and peptides that differ from those predicted from gene sequences can be measured but they generally cannot be identified by database matching, even if the difference is only a single amino acid residue. Thus, it is necessary to develop bioinformatics approaches to generate relatively comprehensive gene inventories for each organism type, which are critical for expression and functional analyses (Banfield et al., 2005).

28.2.5 Environmental Factors Affecting Gene Expression in Soil

Numerous environmental factors can activate or repress gene expression, thus affecting microbial activity, richness and evenness (Daubaras and Chakrabarty, 1992) of microorganisms inhabiting complex environments like soil, characterized by a variety of fluctuating conditions in physical and chemical properties such as texture, structure, nutrient levels, temperature, water content, pH, and oxygen status (Graeme et al., 2003; Silby and Levy, 2004; Hamamura et al., 2008). It is therefore important to study the environmental conditions influencing the growth of microorganisms and their ability to express activities under in situ conditions (Fleming et al., 1993; Borneman and Triplett, 1997; Jensen et al., 1998).

28.2.5.1 Soil Sampling

Microhabitats and microenvironments resulting from heterogeneity are familiar concepts in microbial ecology, and communities and their activities are determined by local environmental conditions at the submillimeter scale. In practical terms, this has implications for sampling strategies (Grundmann and Gourbiere, 1999). For example, molecular analyses are frequently carried out using $1–10\,g^{-1}$ soil samples, which are often homogenized by pooling subsamples prior to analysis, with little knowledge of the extent to which such samples are representative of soil microbial structure, activity, molecular diversity between treatments, and the extent to which this approach leads to loss of important information.

Graeme et al. (2003) have assessed the effects of scale level (macro and micro) and both sample size (10, 1, and 0.1 g)

and distance between samples on the heterogeneity of soil Crenarchaeota community structure using PCR-DGGE analysis of 16S rRNA- and ribosomal DNA-derived profiles. The results showed a higher heterogeneity for Crenarchaeota DGGE profiles of $1\,g^{-1}$ samples and $0.1\,g^{-1}$ samples, excluding any relationship between the archaeal profiles and the distance between 1 and $0.1\,g^{-1}$ samples; although relationships between community structure and distance of separation may occur at a microscale level, attention has to be paid in the interpretation of molecular data in terms of the representativity of the microbial community structure in the soil environment.

28.2.5.1.1 Soil pH

Although the soil pH has numerous effects on physiological, morphological, and metabolic responses of soil microorganisms, as well as the availability of mineral nutrients, only few studies have examined the effects of soil pH on gene expression and most of them were conducted in pure cultures of microorganisms isolated from soil (Richardson et al., 1988; Soto et al., 2004). The influence of soil pH on the diversity, abundance, and transcriptional activity of ammonia-oxidizing archaea and bacteria in acid soil was studied by Graeme et al. (2008), evidencing the effect of pH through the selection of different bacterial and archaea ammonia-oxidizer phylotypes with consequences for nitrification in acid soils. Čuhel et al. (2010) studying the effects of pH on grassland soil denitrifier community have indirectly derived their size and activity through the correlation of $N_2O/(N_2O + N_2)$ fluxes ratio and the *narG*, *napA*, *nirS*, *nirK*, and *nosZ* denitrification genes amount. Results have pointed out how the N_2 emissions were mostly responsible for the differences in the total N fluxes between the pH treatments, as the N_2O emissions were not significantly different.

28.2.5.1.2 Soil Moisture and Temperature

Soil microorganisms are subjected to large variations in water availability; these variations occur at various scales, such as seasonal fluctuations in soil structure, which then impact water availability at the microhabitat level (Torsvik and Øvreas, 2002). The soil temperature varies in response to physical processes occurring at the soil surface. It is thought that fluctuations in temperature can have a profound effect on microbial gene expression in soil. However, studies monitoring effects of water availability and temperature on gene expression in soil are scarce (Axtell and Beattie, 2002). Wertz et al. (2009) have evidenced the weak effects of seasonal climate changes on total and active *nirK* denitrifying community variations in a potato crop field.

28.2.5.1.3 Oxygen Concentrations

Oxygen was found to limit the expression of genes codifying enzymes involved in denitrification and to inhibit the process itself (Baumann et al., 1996; Metz et al., 2003). Certain proteins are expressed at higher activity levels under anaerobic than under aerobic conditions (Lynch and Lin, 1996). However, studies about the effect of oxygen on gene expression in soil are scarce.

28.2.5.2 Nutrient Status

28.2.5.2.1 Carbon

Even though carbon is essential for microbial growth and survival, few studies have examined the effects of carbon substrates on the expression of microbial genes in soil. Van Overbeek et al. (1997) and Koch et al. (2001) studied the carbon limitation effects on the β-galactosidase activity of a biosensor (*P. fluorescens*) with *lacZ* reporter system. The biosensor responded to carbon limitation by increasing the β-galactosidase activity but the response was more variable in soil than in pure culture.

28.2.5.2.2 Nitrogen

The amount and form of soil nitrogen can strongly influence the expression of genes codifying proteins involved in the N cycle. Magasanik (1996) found an increment of activated *glnN* gene in microorganisms, encoding the enzyme glutamine synthetase (GS) and other nitrogen regulatory genes in response to a decrease in ammonium availability. The activation of these genes increased the ability of microorganisms to use small amounts of available ammonium by synthesizing several enzymes (GS and others) and permeases catalyzing N reactions and uptake of N compounds, respectively. The activation of N-regulatory genes in the absence of easily assimilated nitrogen has also been observed by Jensen et al. (1998), who measured the expression of an ammonium-starvation-inducible gene in *P. fluorescens* using promoterless *luxAB* genes. Studies on enzyme activity coupled with gene expression have also shown that nitrogen fixation is induced when nitrogen sources are not available (Bürgmann et al., 2003).

28.2.5.2.3 Phosphorus

Soluble phosphate is often present at levels lower than other essential macronutrients, and consequently, it is often a limiting factor for soil microorganisms (Paul and Clark, 1996) that usually overexpress genes codifying proteins of phosphorus uptake involved in the phosphate-specific transport systems, those codifying phosphatases and those codifying compounds involved in the dissolution of insoluble phosphate minerals (Al-Niemi et al., 1997; Welch et al., 2001).

Studies have been conducted with *E. coli*, where about 30 genes involved in phosphate regulation have been sequenced (Wanner, 1993). It is known that when inorganic phosphate is limiting, the proteins PhoB and PhoR are activated and, in turn, act as transcriptional regulators for the Pho regulon, which consists of many genes involved in the transport and assimilation of phosphate (Makino et al., 1988, 1989).

Data about the direct measure of gene expression in relation to phosphate availability are lacking.

28.2.5.3 Pollutants

A number of microorganisms satisfy their nutritional and energy requirements by degrading pollutants not naturally present in soil. Studies have focused on activity measurements of

functional genes codifying proteins involved in pollutant degradation in soil, whereas others focused on evaluating the bioavailability of heavy metals in contaminated soils before, during, and after bioremediation.

Holden et al. (2002) did not find correlations between surface-active gene expression and pollutant degradation in hexadecane-contaminated sand. Devers et al. (2004), investigating the expression of atrazine-degrading genes (*atz*) in *Pseudomonas* sp. ADP and *Chelatobacter heintzii* using real-time qPCR, detected a twofold higher atrazine degradation efficiency of *Pseudomonas* sp. with respect to *Chelatobacter* sp.

Nota et al. (2008) reported the synthesis of antibiotics in *Folsomia candida* as a response to increased cadmium-induced susceptibility to invading pathogens, probably caused by repression of genes involved in the immune system. Jiang et al. (2008) isolated and characterized heavy metal-resistant *Burkholderia* sp. from Pb- and Cd-contaminated soil.

Extraction of mRNA and RT-PCR analysis, as well as the use of microarrays and bioreporters, can be useful for evaluating bioremediation (Devers et al., 2004; Sharkey et al., 2004).

28.2.6 Conclusion and Outlook

There are information gaps about microbial gene expression in soil due to limits of the present techniques, the complexity of the soil environment, and interpretation of data analysis. To better understand the regulation of microbiological activity, we need to link gene expression with the numbers and activity of the corresponding protein.

Unfortunately, the soil proteomics is still in the infancy stage, and we need to overcome several methodological problems in order to monitor microbial synthesis of proteins in soil. Extraction procedures should give both RNA and proteins representative of both pools of active living soil microbial cells (Bürgmann et al., 2003; Ogunseitan, 2006). In addition, both the transcriptome and proteome should not change during the extraction (Nannipieri, 2006). A better understanding of microbial functioning of soil requires to link gene expression with the relative proteome, and this can have positive effects on the understanding of important processes such as pollutant and waste degradation, resistance mechanisms, in situ toxin production, and cell-to-cell communications.

Concerning metabolomics approaches, recently, a very promising new one, based on the volatile organic compounds (VOCs), named volatilomics has been proposed to support proteomics with the intent to better characterize soil microbial communities structure and activity (Insam and Seewald, 2010). Until now, the investigation of soil VOCs is complicated by a large variability in soil chemical and physical parameters (soil type, nutrient, and oxygen availability) influencing their production by altering the physiological state of the microorganisms. However, once the above reported interrelationships will be robustly established, volatilomics could be a very useful tool to characterize soil microbial communities (McNeal and Heribert, 2009; Insam and Seewald, 2010).

28.3 Stable-Isotope Probing and Its Application in Soil Microbiology

Yin Chen

Deepak Kumaresan

J. Colin Murrell

28.3.1 Introduction

Soil is such a complex environment and the functions of many microorganisms inhabiting it are difficult to predict. In the last few decades, environmental microbiologists have applied many techniques in order to study the structure and function of these organisms in soil (Adamczyk et al., 2003; Huang et al., 2004, 2007; Wagner, 2004; Lechene et al., 2006; Ottesen et al., 2006; Hashsham et al., 2007; Li et al., 2008). Stable isotopes, particularly nitrogen (N) and carbon (C), have been used for decades to understand the function of microorganisms in soil ecosystems. Labeling methodologies enable the introduction of the compounds of interest, and the fate of these compounds in soil can then be followed. Norman and Werkman (1943) performed the first tracer experiment using labeled ^{15}N fertilizer and demonstrated that only 20% of the soybean residues were

taken up by the plant and the rest were incorporated into soil organic matter. Early contributions of ^{15}N trace studies to our knowledge on nitrogen mineralization and immobilization in soil have been reviewed by Winsor (1958). The use of ^{15}N in experiments revealed that nitrogen added to the soil decreased in availability with time (Legg et al., 1971) and the majority of nitrogen was immobilized as amino acids (Cheng and Kurtz, 1963) and amino sugars (Isiriah and Keeney, 1973). Since then, a number of studies have used ^{15}N to understand nitrogen cycling in soil. This has been reviewed in detail by Nannipieri and Paul (2009). Moreover, a variety of labeled carbon substrates such as CO_2, CH_4, glucose, amino acids, and plant organic matter have now been used to address fundamental questions in soil ecology, particularly to understand the carbon transfer in soil–plant system (Stewart and Metherell, 1999), soil microbial respiration (van Vuuren et al., 2000), and soil food web (Middelburg et al., 2000). The role of carbon isotopes in understanding functional soil ecology has been extensively reviewed by Staddon (2004).

Stable-isotope probing is a method for identifying active microorganisms involved in a specific bioprocess. The method relies on the incorporation of stable isotopes (e.g., ^{13}C, ^{15}N) into DNA, RNA, phospholipid fatty acid (PLFA), or protein (Boschker et al., 1998; Bull et al., 2000; Radajewski et al., 2000; Manefield et al., 2002; Jehmlich et al., 2008). Further separation and identification of those labeled compounds can then be carried out to infer the function of the organisms involved. Since the first publication on DNA-SIP (Radajewski et al., 2000), this technique has been used to study active microorganisms in the soil environment. Here, we summarize recent applications of SIP in the study of soil microorganisms.

28.3.2 DNA/RNA-SIP

DNA and RNA stable-isotope probing are extremely powerful tools in analyzing active microorganisms in a particular process. SIP involves several key steps, including incubations with labeled substrate, DNA/RNA extraction and purification, ultracentrifugation, and fractionation (Figure 28.1). Since the first publication of DNA-SIP by Radajewski et al. (2000) and RNA-SIP by Manefield et al. (2002), the number of publications using SIP has increased considerably. Table 28.5 lists a number of
FIGURE 28.1 Flowchart showing major steps in DNA/RNA-SIP analyses. (1) SIP incubations with replicates and ^{12}C-controls; (2) DNA/RNA extraction from incubated samples; (3) separation of labeled and unlabeled DNA/RNA by ultracentrifugation and fractionation and precipitation of DNA/RNA; and (4) downstream analyses of ^{13}C-labeled DNA/RNA.

TABLE 28.5   Recent Studies Using DNA/RNA-SIP to Identify Active Microorganisms in Soils

Substrate	Habitat	Phylogenetic Groups Identified	Marker Genes	Reference
$^{13}CH_4$	Landfill soil with worms	*Methylobacter*; *Methylosarcina*; *Methylocystis*; *Methylomonas*	16S rRNA; *pmoA*; *mmoX*	Héry et al. (2008)
$^{13}CH_4$	Landfill cover soil originally from a peat bog	*Methylobacter*; *Methylomonas*; *Methylocystis*; *Methylocella*	16S rRNA; *pmoA*; *mmoX*	Cébron et al. (2007b)

[a] Aromatic ring-hydroxylating dioxygenase.

recent publications using DNA/RNA-SIP technology to analyze a variety of soil microorganisms involved in different processes.

DNA-SIP relies on the incorporation of a substrate that is highly enriched in a stable isotope, such as ^{13}C, and the identification of active organisms by the selective recovery and analysis of isotope-enriched DNA (Radajewski et al., 2000; Dumont and Murrell, 2005; Manefield et al., 2006). DNA-SIP is a culture-independent method; thus, uncultivated organisms can be identified. DNA-SIP also offers direct access to genomic information of potential novel microorganisms involved in a particular process (Dumont et al., 2006; Chen et al., 2008b; Neufeld et al., 2008). One of the drawbacks of DNA-SIP, however, is the relatively long incubation times that are required for DNA replication and incorporation of the ^{13}C-label into newly synthesized DNA (reviewed in Dumont and Murrell, 2005). This long incubation time can result in potential crossfeeding problems, which makes data interpretation more complicated (reviewed by Dumont and Murrell, 2005; Manefield et al., 2006). However, recent studies have employed minimum labeling to shorten incubation time and eliminate crossfeeding of ^{13}C (e.g., Cadisch et al., 2005; Neufeld et al., 2008).

RNA-SIP, on the other hand, offers greater sensitivity because RNA synthesis occurs at a faster rate than DNA synthesis and it is possible to obtain ^{13}C-labeled RNA more quickly than ^{13}C-labeled DNA (Manefield et al., 2002; Lueders et al., 2004). Enhanced sensitivity by RNA-SIP has been demonstrated in a number of studies (Table 28.5). In addition, since only small amounts of isotope need to be incorporated, near in situ concentrations of substrate can be used in RNA-SIP experiments, therefore minimizing potential biases caused by high substrate concentrations during earlier DNA-SIP experiments (Radajewski et al., 2000, 2002). Since its development, RNA-SIP has been applied in a number of studies, especially in the study of plant rhizosphere–microbe interactions using ^{13}CO$_2$ (Table 28.5). This has yielded a wealth of information on rhizosphere bacterial populations that are sequestering carbon through plant exudates, a process that is poorly understood. Compared with DNA-SIP, one of the drawbacks of RNA-SIP is that only 16S rRNA genes can be analyzed since only isotope-labeled RNA is obtained.

Combining RNA-SIP and DNA-SIP is a particularly powerful strategy since these two techniques are complementary. An excellent example was a study by Lueders et al. (2004), in which they simultaneously analyzed the incorporation of the carbon isotope in ^{13}CH$_3$OH in microcosms containing oxic rice field cover soil for 42 days. RNA-SIP allowed the identification of methylotrophs that were active first in the microcosm when only small amounts of ^{13}CH$_3$OH had been metabolized. DNA-SIP, however, shed light on the primary methanol utilizing communities, their enrichment during the incubation period, and their interactions with fungi in the microbial food web.

Previously, only ^{13}C-labeled substrates were used for SIP. More recently, ^{15}N-labeled substrates have also been used (Cadisch et al., 2005; Buckley et al., 2007a, 2007b) to identify those microorganisms metabolizing nitrogen compounds. Compared with ^{13}C-SIP, the separation of DNA bands between ^{15}N-DNA and ^{14}N-DNA was only 4 mm, which is much less than when labeled

with ^{13}C substrates (10 mm). Thus, a second ultracentrifugation was applied to separate ^{15}N-DNA and ^{14}N-DNA (Buckley et al., 2007a, 2007b). The possibility of using ^{18}O for SIP was also studied recently. Incubating *E. coli* cultures or soil samples with H$_2$^{18}O yielded DNA from actively growing cells that was sufficiently labeled to separate ^{18}O-containing DNA from the background (1.5–3.5 mm; Schwartz, 2007).

28.3.3 Combining DNA-SIP and Metagenomics

Metagenomics is a method to study microorganisms without the prerequisite for cultivation (Handelsman et al., 1998) and can be used to retrieve genetic information directly from the environment by either direct large-scale DNA sequencing or by functional screening of relevant bioactive compounds (reviewed in Handelsman, 2005; Lasken, 2007; Schmeisser et al., 2007; and references therein). In combination with metagenomics, DNA-SIP facilitates the selective isolation of DNA from functionally relevant microorganisms to construct metagenomic libraries in a directed fashion that has not been possible previously (Schloss and Handelsman, 2003; Wellington et al., 2003; Dumont and Murrell, 2005; Friedrich, 2006; Neufeld et al., 2007). This goal was first achieved by exposing a soil sample to ^{13}CH$_4$, retrieving high-quality labeled DNA without damaging through UV exposure, and generating a modest bacterial artificial chromosome (BAC) library for the discovery of a BAC clone, which contained a *pmoCAB* operon (Dumont et al., 2006). However, the major concern of combining DNA-SIP with metagenomics has been the challenge of obtaining sufficient ^{13}C-labeled "heavy" DNA for construction of a metagenomic library, without using excessively high concentrations of substrate and reducing the risk of enrichment bias. This has been recently overcome by applying multiple displacement amplification (MDA) to generate large quantities of DNA from minute quantities of ^{13}C-labeled "heavy" DNA (Chen et al., 2008b; Neufeld et al., 2008). In addition, by combining DNA-SIP and high-throughput sequencing technology, Kalyuzhnaya et al. (2008) have managed to reconstruct the genome sequence of a key methylamine degrader from Lake Washington, which had not been previously cultivated.

28.3.4 PLFA-SIP

Lipids found in cellular membrane with other biomarkers such as sterols, hopanoic acids, and ether lipids can be used to differentiate bacteria, fungi, and algae (Boschker and Middelburg, 2002), among which phospholipid fatty acids (PLFAs) have been extensively used as microbial biomarker. The use of stable isotopes such as ^{13}C-CH$_4$ or acetate as substrates and subsequent analysis of the isotope-labeled PLFA revealed the phylogenetic identity of microbes actively utilizing the substrate. Gas chromatography–combustion–isotope ratio mass spectrometry (GC/C/IRMS) can be used to measure the natural variation in isotope ratios of compounds such as ^{13}C and ^{12}C carbon isotopes. GC/C/IRMS can detect minor changes in stable-isotope composition, and traditionally, it has been used to compare the

δ13C values (relative abundance of ^{13}C to ^{12}C) of microbial lipids used as biomarkers in geological studies to study ancient environments (Boschker and Middelburg, 2002). The extraction of PLFA from natural samples and the analysis of PLFA by GC/C/IRMS have been reviewed in detail by Evershed et al. (2006) and Boschker and Middelburg (2002).

Boschker et al. (1998) demonstrated the first use of PLFA-SIP to show that type I methanotrophs dominate methane oxidation at a freshwater site using ^{13}C-CH_4 as substrate. Moreover, the authors also revealed that *Desulfotomaculum acetoxidans* was the predominant organism involved in the sulfur cycle in the estuarine and brackish sediments using ^{13}C-acetate. Since then, a large number of labeled substrates (such as bicarbonates, CO_2, toluene, and propionate) have been used to understand the role of microbes in different environments (see review by Evershed et al., 2006).

One of the major contributions of PLFA-SIP is to link function with microbial diversity particularly with methanotrophic bacteria in soil environment (Table 28.6). The presence of distinct PLFAs in methanotrophic bacteria allows us to differentiate between type I (16 carbon fatty acids: 16:0, 16:1) and type II (monosaturated 18 carbon fatty acids: 18:1ω9c, 18:1ω8) methanotrophs and from all other organisms. PLFA-SIP has been successfully used to investigate methanotroph population in sediments (Boschker et al., 1998), soils (Knief et al., 2003; Chen et al., 2008a; Maxfield et al., 2008; Shrestha et al., 2008), microbial mat (Blumenberg et al., 2005), and peat bogs (Raghoebarsing et al., 2005). Owing to the sensitivity of the PLFA-SIP technique (the need for low incorporation of labeled substrate), it has been a preferred tool to study high-affinity methanotrophs, which oxidize methane at atmospheric concentration (2 ppmv) (Bull et al., 2000; Maxfield et al., 2006, 2008). Moreover, PLFA-SIP needs significantly lower amounts of stable-isotope incorporation into microbial biomass than DNA- and RNA-SIP. This eliminates any possibility of crossfeeding, which is one of the potential drawbacks of DNA-SIP.

PLFA-SIP has also been extensively used to study plant–microorganism interactions either in laboratory incubations or in situ studies using ^{13}C-CO_2 pulsed labeling of growing plants (Treonis et al., 2004; Prosser et al., 2006; Williams et al., 2006; Lu et al., 2007). Butler et al. (2003) used ^{13}C-CO_2 pulsing to analyze the incorporation of plant exudates into PLFAs in the bulk and rhizosphere soils of annual ryegrass (*Lolium multiflorum* Lam. var. Gulf) grown in a greenhouse. By analyzing the PLFAs, the authors were able to show differences in the ways in which plant exudates are cycled through microbial communities during different stages of plant development. Prosser et al. (2006) have reviewed the application of stable isotopes in studying plant–microorganism interactions. PLFA-SIP has also been used to link members of the microbial community with degradation of specific xenobiotic compounds such as toluene (Hanson et al., 1999) and styrene (Alexandrino et al., 2001). Alexandrino et al. (2001) used ^2H to identify styrene-degrading organisms in a biofilter.

A key limitation of the PLFA-SIP technique is that even in well-characterized microbial groups such as methanotrophs and sulfate reducers with an extensive PLFA database, it is only possible to detect organisms at the genus level. In addition, recent studies by Dedysh et al. (2007) and Dunfield et al. (2007) have revealed some discrepancies in the PLFAs present in methanotrophs. Dedysh et al. (2007) demonstrated that the type II methanotroph *Methylocystis heyeri* contains 16:1ω8c PLFA, which was previously considered to be a signature PLFA for type I methanotrophs. Therefore, studies have overcome this limitation by combining PLFA-SIP with other complimentary techniques. Chen et al. (2008a) successfully combined PLFA-SIP and mRNA-based analysis to investigate the active methanotroph community structure in peatlands and moorlands under the plant cover of *Sphagnum/Eriophorium* and *Calluna*, respectively. By combining PLFA-SIP with mRNA-based analysis, the authors were able to take the advantage of the sensitivity of the PLFA-SIP while getting a better taxonomic resolution with mRNA-based analysis. Another study by Webster et al. (2006) used PLFA- and DNA-SIP with low concentrations of ^{13}C substrate to provide information on carbon flow and functional diversity in sulfate-reducing marine sediment enrichment slurries.

PLFA-SIP technique provides a powerful culture-independent approach to link function with microbial diversity in different environments and is more sensitive than DNA- and RNA-SIP. The methodology allows us to link microbial diversity with processes at significantly lower concentrations of substrate, which could potentially mimic the substrate concentration in natural environments (such as atmospheric concentrations of methane). However, the PLFA database is rather limited, and, therefore, the taxonomic resolution is not as significant as can be achieved

TABLE 28.7   Comparison of DNA, RNA, PLFA, and Protein-SIP

SIP	Advantages	Disadvantages
DNA-SIP	• Less labor intensive • Instrument requirement is minimal • Whole genomic DNA is available for downstream analyses (e.g., functional gene analyses, genome reconstruction)	• Long incubations required • Potential crossfeeding of labeling • Less sensitive
RNA-SIP	• More sensitive than DNA-SIP • Requires less labeling therefore minimizes crossfeeding	• Only ribosomal RNA gene can be analyzed • Labor intensive • Difficulty in RNA extraction from soil
PLFA-SIP	• Very sensitive • Can be used for quantification of relative bacterial abundance	• Taxonomic assignment of PLFA is troublesome due to the lack of complete database • Labor intensive • Require special instrument
Protein-SIP	• Very sensitive due to the high sensitivity of MS	• Requires metagenome sequences prior to experimental setup • Extremely labor intensive • Requires special instrumentation

with DNA/RNA-based methods. As the use of isotope labeling expands with new substrates and novel environments, PLFA-SIP in combination with other complimentary techniques should continue to provide new insights into microbial ecology, as the PLFA database for microorganisms continues to grow.

28.3.5 Recent Advances and Outlook

There is no doubt that SIP will continue to be an important tool for soil microbiologists to elucidate the function and structure of soil microorganisms. All three SIP techniques have their advantages and disadvantages (Table 28.7) and need to be carefully selected. This largely depends on specific situations. PLFA-SIP is the most sensitive technique and can be used to quantify the activity of certain organisms. However, the lack of a complete database for PLFAs makes it difficult for taxonomic assignment. RNA-SIP, on the other hand, is a powerful tool to reveal the diversity of microorganisms assimilating labeled substrate since labeled RNA can be separated from unlabeled RNA. However, DNA-SIP is desirable in some cases where the whole genomic DNA is needed, although it is the least sensitive technique and requires longer incubation times for sufficient labeling of DNA. One of the main advantages of DNA-SIP is that the labeled DNA can be used for functional gene analyses and for whole-genome/metagenome analyses. This method therefore can considerably link the function of microorganisms to specific processes. The best approach, where possible, will be to combine all these techniques to study the functions of microbes in an environmental sample.

Although DNA/RNA and PLFA-SIP offer links between microbial community and function, the most direct link is proteins since they actually catalyze the biochemical reactions. Very recently, a proof of concept for protein-SIP has been published (Jehmlich et al., 2008). The authors analyzed protein from a single bacterial species (*Aromatoleum aromaticum* strain EbN1, a toluene degrader) within a microbial consortium (the other members of the consortium cannot metabolize toluene but can use gluconate), which were fed with $^{13}C_7$-toluene and ^{12}C-gluconate.

Labeled proteins were separated by two-dimensional gel electrophoresis and MS to follow the ^{13}C carbon atoms into proteins of strain EbN1 and to identify these proteins. The authors demonstrated that incorporation of ^{13}C was exclusively found in proteins from strain EbN1, the toluene degrader, which acquired carbon from ^{13}C-toluene. They therefore demonstrated the suitability of protein-SIP to identify metabolic active species within a mixed culture. Although a powerful technique, protein-SIP requires metagenome sequences prior to the identification of labeled proteins, and this can be time-consuming and expensive. With the continuous progress in high-throughput DNA sequencing technology, this might be affordable in the near future.

In summary, SIP is a useful tool for soil microbiologists and can be used to characterize many functions of soil microorganisms and to reveal the dynamic changes in soil microorganisms in response to changes in soil environments.

Pedology

Larry T. West
United States Department of Agriculture

Larry P. Wilding
Texas A&M University

PEDOLOGY IS THE EARTH SCIENCE that quantifies the factors and processes of soil formation including quality, extent, distribution, and spatial variability of soils from microscopic to megascopic scales (Spositio and Reginato, 1992; Wilding et al., 1994). Spatial distribution and variability of soils in landforms is governed by the processes of soil formation which are, in turn, interactively conditioned by lithology, climate, biology, and relief through geologic time. Soils form a continuous drape across the landscape and are intimately linked to one another; processes and impacts on higher topographic surfaces directly affect adjacent lower lying surfaces. This is because transfer of energy and mass, the driving forces of pedogenesis, occur within, over, and among 3D soil landform components. Renewal vectors of biomass input, rainfall, and dust counter constituent losses via drainage waters, lateral interflow, and downslope migration of erosion products.

The development of open versus closed drainage patterns during landform evolution strongly governs energy and mass flux in the system. In the closed drainage network, dispersal of chemical and erosion products is distributed to adjacent local sinks and depressions. In contrast, dispersal is mostly external to source areas in open drainage systems. In this case, distribution occurs via upland drainage ways to tributary streams, rivers, lakes, and oceans. Differences in drainage network are paramount when one considers the effect of landscape on soil moisture and nutrient regimes, environmental contamination, recharge of groundwater aquifers, crop production potential, etc. Hence, to adequately comprehend, interpret, and transfer knowledge of soil resources from one area to the next, a systematic soil/geomorphic landscape model must be applied.

Through knowledge of soil/landform relationships, pedologists have verified the occurrence, configuration, depth, and pedogenic formation of root and water restrictive layers; documented the origin and distribution of cracking and fissuring patterns in soils and geologic materials that govern bypass flow of nutrients, chemicals solutes, and fluids; identified the scale, mode, and occurrence of systematic soil spatial distribution to aid the design efficiency and sampling of soil units; and used soil color patterns on a macro- and microscale to infer major periods of soil aeration/reduction and relative periods of excess, sufficiency, an deficiency of soil moisture contents for specific land uses. In most soil systems, reaction kinetics and diffusion rates rather than thermodynamic equilibria control chemical reactions, solute movement, and precipitation of chemicals and minerals. These and other impacts of geomorphology and pedogenic processes reflected in soil landscape patterns are covered in Chapters 29 and 30, respectively.

Pedology is an integrative and extrapolative science. It provides an organizational framework to catalog modes, mechanisms, and magnitudes of soil spatial variability, and to generalize this knowledge for synthesis and data population for models. Pedology provides a vehicle for extrapolation and scaling of spatial variability from components of soils (individual particles, aggregates, hand specimens, and horizons) to the populations of soils comprising the landscape as a whole (pedons, toposequences, watersheds, physiographic regions, and the pedosphere) (Figure 34.1). Figure 34.2 illustrates hierarchical levels in this continuum of soil organization relative to tools used to generalize information content at multiple scales of resolution.

Various taxonomic systems have been developed to accommodate this cataloging of soil attributes and their landscape distribution. *Soil Taxonomy* (Soil Survey Staff, 1998, 2010) is such a system developed using morphogenetic indicators (diagnostic

horizons and properties) as class criteria. Chapter 31 discusses the history leading to the development of *Soil Taxonomy*, an overview of class criteria, nomenclature, and interpretational inferences. Although *Soil Taxonomy* was developed to categorize soils from across the globe, the functions and objectives of it and other systems of soil classification systems, including the French, Canadian, Russian, and Chinese systems, often have a national bias. To enhance international understanding of and ability to communicate about the soil resource, FAO with support from the International Union of Soil Science (IUSS) is leading the development of the World Reference Base for Soil Resources (http://www.fao.org/docrep/w8594e/w8594e00.htm), and the IUSS is providing leadership for development of a universal soil classification system to enhance our ability to categorize, understand, and extrapolate knowledge of the global soil resource.

Spatial variability in soil systems belongs to two broad categories: systematic (structured) and random (unstructured and unknown causes). Systematic variability is a gradual or marked change in soil properties as a function of physiography, geomorphology, and the interactions of the soil forming factors (Wilding and Drees, 1983) and our ability to predict systematic soil change across the landscape is based on the soil–landscape paradigm (Hudson, 1991). Systematic variability permits pedologists to partition spatial variability in soils by subsets of properties that constitute soil survey map units corresponding to geomorphic landscape elements. The purpose of soil surveys is to partition the spatial variability of landforms into stratified subsets that are less variable than the landscape as a whole and to remove systematic error from the population of soils. Information gained from soil surveys on the quality and distribution of soils when correlated with their classification provides a power vehicle for transfer of knowledge of soil properties and appropriate technologies for sustainable management. Chapter 33 illustrates characteristics of soils in each of the 12 soil orders in *Soil Taxonomy*, their properties, processes, and distribution patterns on a global scale. Each of the 12 soil orders are addressed as a subset of this chapter.

Pedologists are being challenged to better integrate information on soil properties, processes, and distribution into assessments of food and fiber production, soil quality, environmental sustainability, ecosystem services, and risk avoidance. Land evaluation, the consideration of actual and potential land use as a function of land properties, can be realized with qualitative methods, but increasingly quantitative simulation models are used together with geographic information systems (GIS) as aids for land use decisions. These models and GIS systems need to be fed with adequate soil data, but use of databases with little attention to natural soil dynamics or landscape relationships may lead to unrepresentative results. Chapter 34 discusses both classical qualitative and modern simulation methods of land evaluation. This chapter illustrates land evaluations through case studies for both data-rich and data-poor scenarios, and outlines the role of pedology and soil survey in land use decisions for sustainable ecosystems.

Pedology is adapting to the demand for more data, better methods, and new approaches to address complex natural processes that strongly influence our ability to interpret soil behavior and design management systems that maintain or enhance soil function in an ecologically and environmentally sustainable manner. The remaining chapters in this section describe a selected set of these new areas of study and application that likely will be important pedological subdisciplines in the twenty-first century.

Hydropedology is a combination of pedology, hydrology, and soil physics disciplines that addresses soil and water interactions. It addresses multiscale basic and applied pedologic and hydrologic processes and their properties in the variably unsaturated zone (Lin, 2003). Hydropedology focuses on the synergistic integration of pedology and hydrology to enhance our understanding of soil–water interactions and landscape–soil–hydrology relationships across space and time as they relate to ecosystem functions. Chapter 35 provides an overview of the fundamentals and applications of hydropedology, including a review of principles and description of recent advances in soil architecture and preferential flow, soil hydromorphology, scaling, pedotransfer functions, and coupling biogeochemistry with hydropedology.

Subaqueous soils, those soils inundated with water almost continuously (positive water pressure at the soil surface for at least 21 h each day in all years), are found along oceanic coastal margins and in shallow water associated with lake margins. Historically, these subaqueous substrates were considered to be sediments instead of soils. Recent research in these important ecosystems, however, have shown that subaqueous soils are, in fact, soils with horizons and properties that are the result of pedogenic processes. Chapter 36 provides an overview of subaqueous soils including the history of their recognition as soils, descriptions of methods for characterization and mapping, subaqueous soil classification, genesis models, and examples of interpretation of properties and distribution for soil use and management.

The explosion in computation and information technology has motivated numerous initiatives around the world to build spatial data infrastructures including regional, continental, and worldwide soil databases. In soil science, the principal manifestation is soil resource assessment using GIS to produce digital soil property and class maps with the limited expensive fieldwork and laboratory analysis. Digital soil mapping refers to the production of spatial soil databases that are based on soil observations combined with environmental data through quantitative statistical relationships. It uses a range of technologies for more accurate and efficient prediction of soil properties through optimal sampling strategies, rapid analysis of soil properties, and rapid acquisition of environmental variables over large areas and can be thought of as a means for modernizing and systematizing traditional soil survey. Chapter 37 describes the development of and theory underlying digital soil mapping and reviews the various approaches with examples.

Pedologists have long recognized that soils change over time. With a few exceptions, however, this change has mostly been related to changes over the course of geologic time and landscape development. Recently, greater emphasis has been placed

on the concept of soil change as it relates to the domestication of soil over historic time; the transformation of soil into a cultural–historic–natural system. To understand soil change and apply that knowledge to sustainable land management, we must understand how human activities impact the soil itself and soil's interactions with the wider environment. Chapter 38 discusses soil change including its impacts on soil function and ecosystem services, approaches to evaluate soil change, factors and mechanisms affecting soil change, and speculates on the future science and management of soil change.

The demand for more and more comprehensive data on soils as they vary across the landscape led to development and evaluation of numerous methods to rapidly evaluate soil properties on samples in the laboratory, at specific sites in the field, continuously across the landscape, and for fields or larger-sized areas. Among these techniques are diffuse reflectance infrared spectroscopy, gamma-ray spectroscopy, x-ray fluorescence, electromagnetic induction, and ground-penetrating radar. Advances in technologies to allow instrument portability and enhanced data analysis have made these technologies more commonly available for pedological research and soil inventories. Chapter 39 discusses two of these technologies, ground-penetrating radar and electromagnetic induction including the theory behind the technologies, initial uses, and their application to pedological studies.

29.1 Introduction

Soils form a continuum across the earth's land surface, that is, the interface of atmospheric, biological, and geological processes. Soils are more than a veneer of surficial alteration on landscapes or sediments. Soils, landscapes, and surficial sediments or rocks together comprise 3D systems that coevolve through the interaction and balance of physical and chemical weathering versus erosion and deposition. One must comprehend the relationships among soils, landscapes, and surficial sediments to fully understand soil landscapes, successfully predict soil occurrence, and anticipate soil behavior. Soil geomorphology is the scientific study of the origin, distribution, and evolution of soils, landscapes, and surficial deposits and

the processes that create and alter them. As a science, soil geomorphology is directly linked to pedology, geology, hydrology, archaeology, geomorphology, physical geography, ecology, and geotechnical engineering (Figure 29.1). Soil geomorphology relies primarily, but not solely, upon geological principles and techniques (Daniels and Hammer, 1992). Geologic/geomorphic processes substantially, but not solely, determine the materials from which soils are derived via the nature and redistribution of sediments. Principles and techniques drawn from geology or from other sciences often have applications or expressions that are unique to soils and soil landscapes. This chapter summarizes the major geomorphic principles and techniques used to understand the relationships among soils, landscapes, surficial sediments (Hunt, 1986), and internal water movement.
FIGURE 29.1 Conceptual diagram showing the relationships of soil geomorphology and other sciences.

29.1.1 Goals of Soil Geomorphology

Soil geomorphology serves two important capacities: (1) Geomorphic-based landscape models allow the segregation of the soil continuum into meaningful natural soil bodies that explain soil distribution from hillslope to continental scales. (2) It provides basic principles for understanding the geomorphic history of landscapes (e.g., spatial and time relationships among soils, landscapes, and surficial sediments).

29.2 Key Terminology

Before discussing the principles of soil geomorphology in detail, a few key definitions are needed. Although some terms may have alternate definitions, our discussion uses those following.

29.2.1 Depositional Surface

Depositional surface is a part of a geomorphic surface formed by the deposition of sediments (alluvial, colluvial, eolian, etc.) derived from an erosional surface or erosional processes (Ruhe, 1975). Water, wind, ice, and gravity are active agents that construct and shape depositional surfaces with water being the most universally prevalent agent.

29.2.2 Erosional Surface

An erosional surface is a part of a geomorphic surface formed by removal of rock, soil, or sediment under the wearing and transport action of water, wind, ice, and gravity (Ruhe, 1975). Running water is the dominant agent that forms and shapes most erosional surfaces (wind, ice, or gravity dominant agent in select settings).

29.2.3 Geomorphic Surface

A geomorphic surface is a definable land surface area that forms during a given time under a common set of erosional and depositional processes. A geomorphic surface may include multiple landforms, but it is a mappable spatial area based upon geomorphic techniques and field observations that has specific and identifiable borders (Ruhe, 1975).

29.2.4 Landform

A landform is any physical, recognizable feature on the earth's surface, having a characteristic shape and internal composition that is produced by natural processes (SSSA, 1997). Landforms are the individual features of the earth that together comprise the land surface (Ruhe, 1975).

29.2.5 Landscape

A landscape is a spatially adjacent collection or assemblage of landforms that can be observed in a single view or from a given vantage (Ruhe, 1975). The landforms that compose a single landscape may have the same age and origin or may vary in both age and origin. Another definition for landscape is the portion of the land surface the eye can comprehend in a single view (Ruhe, 1969).

29.2.6 Pedon

A pedon is a 3D soil body l with lateral dimensions large enough to permit the complete study of horizon shapes and relations. A pedon ranges from 1 to 10^2 m in land surface area and has a maximum defined depth of 2 m (SSSA, 1997).

29.2.7 Soil

Soil is a natural, 3D body with definable boundaries that occurs on the land surface composed of solids (mineral and organic), liquids (water), and gases. Soil is characterized by horizons distinguishable from the initial material as a result of additions, losses, transfers, and transformations in the surface environment and/or by the ability to support higher plant forms (Soil Survey Staff, 2010).

29.2.8 Soil Delineation

Soil delineation is an individual polygon shown on a soil map with a map unit symbol and name that defines a 3D soil body of specified area, shape, and location on the landscape (SSSA, 2010).

29.2.9 Soil Map Unit

A soil map unit is an aggregate of all soil delineations in a soil survey area that have a similar, established set of characteristics (Van Wambeke and Forbes, 1986). Each delineation of a soil map unit is identified by the same symbol and name in a soil survey.

29.3 Soil as a Landscape Unit or Body

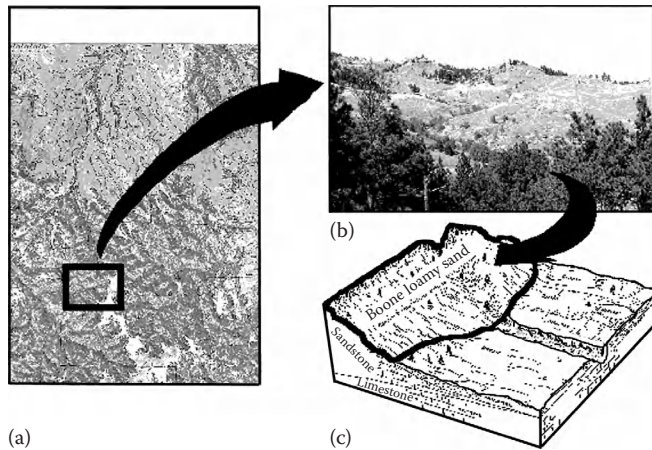
Soil geomorphology is a field science that studies soils on landscapes. The soil continuum on a landscape, for ease of comprehension, is divided into discrete individuals. The pedon is the soil unit most commonly described, sampled, and classified by pedologists. The relative size or scale of a pedon is an intellectual


FIGURE 29.2 (a) Landscape image, (b) soil map image, and (c) block diagram showing soil as a landscape unit.

FIGURE 29.3 Conceptual diagram of Jenny's five soil-forming factors climate, biota, parent material, topography, and time.

construct useful and functionally necessary for description and classification. Pedons, however, lack distinct lateral boundaries and are, therefore, not natural landscape units. Geological processes, which are driven by the atmospheric agents of water, wind, ice, and gravity, impact landscapes as a continuum. Landscapes, however, possess natural internal boundaries that restrict or control mass and energy transfer. Examples of such boundaries are topographic divides, contacts between different rocks or sediment bodies, inflections in slope gradient or shape, and contacts between landforms of different age, origin, and internal structure.

29.3.1 Landscape Scale and Function

Soil delineations depicted on a soil map at or near a scale of 1:24,000 are more closely linked to geomorphic processes than are individual pedons. Accordingly, soil delineations (groupings of similar pedons) are better suited to geomorphic studies than individual pedons. Soil delineations depicted in a soil survey are landscape units (Figure 29.2). Boundaries between delineations are established by the soil surveyor, but not in an arbitrary fashion. Boundaries on a soil map delimit observable differences in soil morphology such as horizon type and thickness, and soil color, texture, and structure across the landscape. Changes in soil morphology across a landscape generally result from differences in the transfer of mass and energy driven by ecological, geomorphic, or atmospheric processes. Soil surveyors use observation, experience, and geomorphic landscape models to create soil maps.

29.4 Models of Soil Formation

Soils are complex systems that defy easy comprehension. Therefore, we use scientific models to help understand or explain soils. No single model provides complete understanding. Models of various form, function, and design are needed to understand
systems as complex as soils (Dijkerman, 1974). Two important and well-known soil models are those of Jenny (1941) and Simonson (1959).

29.4.1 Jenny's Factors of Soil Formation

The eloquent, conceptual model of Jenny (1941) describes soil as a function of climate, biological influences, topography, parent material, and time (Figure 29.3). Implicit in this model are the distinct relationships among ecosystems (biological factor), landscapes (topography), surficial sediments (parent material), and landscape evolution (time). Stratigraphy of sediments or bedrock and surface contours strongly influence the movement of water within and over the landscape. Topography and parent materials have a strong control on both local (e.g., soil water tables, water holding, nutrient capacity, salt content, soil temperature) and regional soil environments (e.g., rain shadows, elevational induced climate zones, adiabatic winds) and therefore impact ecosystem form and function. All five soil-forming factors are linked either directly or indirectly to landscapes, surficial sediments, and landscape evolution.

29.4.2 Simonson's Process Model

Simonson (1959) explained soil formation through the interaction of four processes: additions, removals, translocations, and transformations (Figure 29.4). This model is more helpful than Jenny's (1941) for understanding the spatial relationships within soil landscapes. Geologic or geomorphic processes cause additions, removals, translocations, and transformations on a landscape scale that create and modify landforms, sediments, and soils. For example, sediment eroded from the flank of a hillslope is deposited as colluvium at the base of the slope or as alluvium in nearby drainageways or floodplains. The sediment is incorporated into the uppermost horizons of an existing soil or becomes fresh parent material in which a new soil begins to form.

Additions
Water as precipitation, condensation and runoff
O, N, and CO_2, and dust from the atmosphere
Organic matter by the biosphere
Sediment by slope or water deposition
Energy by solar radiation.

Losses
Water by evapotranspiration
N by denitrification
CO_2 by organic matter oxidation
Sediment removal by erosion
Energy by radiational cooling

A Horizon

Transformations
Organic matter humification
Particle size reduction by weathering
Soil structure formation
Redox concentrations and depletions
Clay mineral alterations

Translocations
Clay, organics, sesquioxides by water
Plant nutrient uptake and cycling
Soluble salts in water
En masse by fauna

B Horizon

C Horizon

Losses
Water including chemicals in solution
and colloids in suspension

FIGURE 29.4 Simonson's (1959) process model of soil genesis showing the interactions of additions, removals, transfers, and transformations.

29.5 Soil Landscape Models

29.5.1 The Catena

The models of Simonson (1959) and Jenny (1941) provide an important conceptual framework for understanding soil formation. Neither model, however, establishes functional boundaries for segregating the soil continuum into natural landscape units. The catena is a fundamental concept that explains the soils pattern on hillslopes. Milne (1936a) coined the term catena to describe a repeating sequence of soils that occurs from the hillslope top to the adjacent valley bottom. Milne (1936a, 1936b) distinguished two catena types. The first type occurred on hillslopes developed over a single kind of parent rock. Despite the uniformity in parent rock, Milne observed a sequential change in soils along the slope gradient. Milne attributed the sequence of soils to variations in subsurface drainage, lateral transport of sediments, and the translocation of materials at or beneath the soil surface (Figure 29.5a).

In Milne's (1936a, 1936b) second example, the hillslope contained more than one type of parent rock (Figure 29.5b). An observable sequence of soils also occurred on this hillslope. Variations in drainage and lateral transport also produced this catena, but stratigraphic differences in the parent rock increased the complexity of the soil pattern. In this example, the surficial sediments form a drape on the landscape that is not coincident with the underlying rock strata. The catena concept includes both surficial stratigraphy and internal hillslope structure or lithology.

Furthermore, the catena concept is both a soil landscape model and a geomorphic model or system. Milne (1936a) recognized that lateral sorting contributed to the sequential soil variation down the hillslope. Erosion and sedimentation processes driven by relief and water movement redistribute sediments across hillslopes creating subtle lateral differences in soil parent materials (Kleiss, 1970). Recall that both parent material and topography are factors in Jenny's (1941) model of soil formation. The same erosional and depositional processes that drive landscape evolution influence the soil pattern on landscapes. The sequential change in soil morphology across a landscape is linked by process to landscape evolution on hillslopes both in time and space. In Jenny's model, landscape evolution means that parent material and topography are not independent variables, but rather are dependent variables that can covary in time.

A well-studied catena consists of the Clarion–Nicollet–Webster soils that occupy about 31,000 km^2 of the Des Moines Lobe in south-central Minnesota and north central Iowa (Figure 29.6). The Des Moines Lobe represents the last Late Wisconsinan glacial advance into Iowa about 14,000 YBP (Ruhe, 1969). Major topographic areas include hummocky, high-relief end moraines separated by undulating areas of low- to moderate-relief ground moraine (Ruhe and Scholtes, 1959; Ruhe, 1969; Kemmis et al., 1981). Closed, semiclosed, and linked depressions occur throughout the Des Moines Lobe, but closed depressions are most abundant in the end moraines (Kemmis, 1991). The Clarion–Nicollet–Webster soils are mollisols formed in a stratigraphic sequence composed of hillslope sediments, supraglacial sediments, and loam-textured till. The catenary relationships on the Des Moines Lobe landscape result from surficial sorting during deglaciation (Kemmis, 1991; Steinwand and Fenton, 1995), postglacial hillslope sorting (Walker, 1966; Burras and Scholtes, 1987; Steinwand and Fenton, 1995), and subsurface flow relationships (Steinwand and Fenton, 1995).
FIGURE 29.5 Two-dimensional diagram of Milne's (1936a, 1936b) catena showing idealized landscape relations.

Numerous studies (Dan and Yaalon, 1964; Blume and Schlichting, 1965; Blume, 1968; Walker and Ruhe, 1968; Huggett, 1975; Pennock and Vreeken, 1986; Pennock and Acton, 1989) have confirmed that catena relationships occur in various climates and landscapes. Conacher and Dalrymple (1977) and Dalrymple et al. (1968) provided a quantitative description of the catena. They defined the soil hillslope relationship as a 3D unit having arbitrary lateral dimensions extending from the hilltop to the valley bottom and from the soil surface to the base of the solum. They segmented the hillslope into nine land surface units (Figure 29.7) based on soil morphology, mobilization and transport of soil constituents, redeposition of soil constituents by overland and throughflow, or by gravity as mass movements.

29.5.2 The Toposequence

Bushnell (1942) studied morphological differences in soils across a hillslope gradient. The soils differed mainly in color. He attributed the changes in morphology to elevational position and local hydrology. This concept is commonly referred to as a toposequence. Unlike Milne, Bushnell did not recognize the influence of hillslope erosion and sedimentation. The terms catena and toposequence are often presently used as synonyms, but the original meanings are not identical.

29.5.3 The Valley Basin

Huggett (1975) expanded on the catena concept proposing that the basic 3D unit of the soil landscape is the first-order valley basin. The functional boundaries of this soil landscape are defined as the atmosphere–soil interface, the weathering front at the soil base, and the drainage basin divides. The topographic boundaries of a drainage basin define the physical limits and direction of overland flow and thus control geomorphic processes such as erosion, transport, and deposition. Also, groundwater divides are generally coincident with topographic divides that are boundaries for overland flow. Thus, the first-order basin forms the natural boundary conditions for chemical and colloidal transport and redistribution via water transport on most landscapes (Figure 29.8a). First-order basins connect to higher order basins forming a larger, linked system across landscapes.

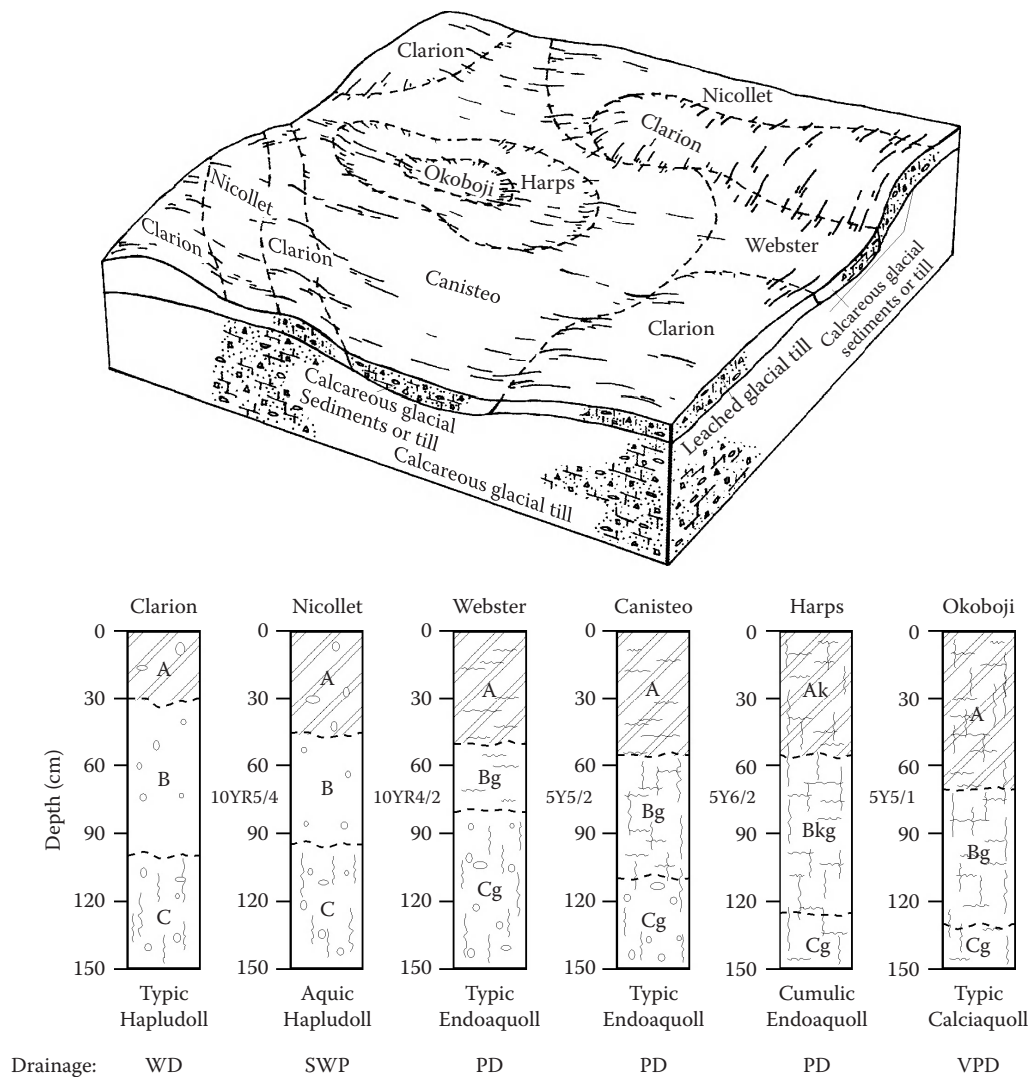
The partitioning of water into surface and subsurface flow is an important component of both Huggett's (1976) watershed model and the catena. Surface runoff or overland flow is the mechanism that drives geomorphic processes. Water that enters the soil drives chemical and biological reactions and via throughflow transports soluble or colloidal materials. The movement of water and associated materials through the soil landscape occurs as both saturated and unsaturated flow. Transport


FIGURE 29.6   Two-dimensional diagram showing the landscape relations of the Clarion–Nicollet–Webster catena.

of material can occur between or within soil horizons, between soils at different landscape positions, or across an entire watershed. Deep percolation can transport material beyond the depth of a soil profile. A 3D approach must account for lateral, divergent, and convergent throughflow. Recent studies (Arndt and Richardson, 1989; Knuteson et al., 1989; Steinwand and Richardson, 1989), as well as earlier work (Glazovskaya, 1968; Cleaves et al., 1970; Crabtree and Burt, 1983), attest to the importance of throughflow and the geochemical link between soils, hydrology, and landscapes.

29.5.4 Open Basins

Drainage basins are either open or closed (Ruhe, 1969). An open drainage basin is confined by the head of the watershed and the perimeter divide. The mouth of the basin is open (Figure 29.8a). Surface water collected within the basin during precipitation events discharges through the outlet at the mouth. Eroded sediment can

be transported and redeposited either within the basin or removed entirely from it. Both mass and energy can enter and leave an open basin by surface flow or runoff. The sediment retained within an open basin represents only a portion of the total sediment produced by erosion. The sediment package in an open basin is an incomplete record of the geologic history. A study of the sediment stratigraphy, therefore, yields only a partial understanding of the geomorphic evolution of the basin.

29.5.5 Closed Basins

Closed drainage basins lack a surface outlet. The drainage pattern within the basin flow to a central area or point (Figure 29.8b). No surface water leaves the basin as runoff. Water from precipitation is lost by evaporation or transpiration or infiltrates and becomes subsurface water. Mass and energy transfers driven by surface flow or runoff occur only within the basin. Surface flow does not remove mass from the basin in the form of clastic sediment. Mass can only
FIGURE 29.7 Two-dimensional nine unit soil and hillslope model (Dalrymple et al., 1968; Conacher and Dalrymple, 1977) showing soil hillslope relationships.
FIGURE 29.8 Three-dimensional diagram (a) open (Schoeneberger and Wysocki 1997) and (b) closed drainage basins as soil landscape models. (Modified from Walker, P.H., and R.V. Ruhe. 1968. Hillslope models and soil formation. I. Closed Systems. Trans. 9th Int. Congr. Soil Sci. 4:561–568.)

be lost as soluble or fine colloidal material in subsurface water. Mass can be removed or added to the basin by eolian processes, but the system is closed to surface runoff. The alluvial sediment contained in a closed basin forms a complete record of its erosional history.

The geomorphic concept of surface runoff that defines open versus closed basins is independent of scale. Open basins span the range from tiny, erosional rills on a hillslope to continental scale drainage basins like those of the Amazon or Mississippi rivers. Likewise, closed basins vary in size from small depressions like tree-tip pits to large tectonic basins such as Death Valley. The similarity is the lack of a surface outlet. The magnitude and complexity of the transfer processes within a basin increase with size. Surface flow never removes mass or energy from a closed basin regardless of size.

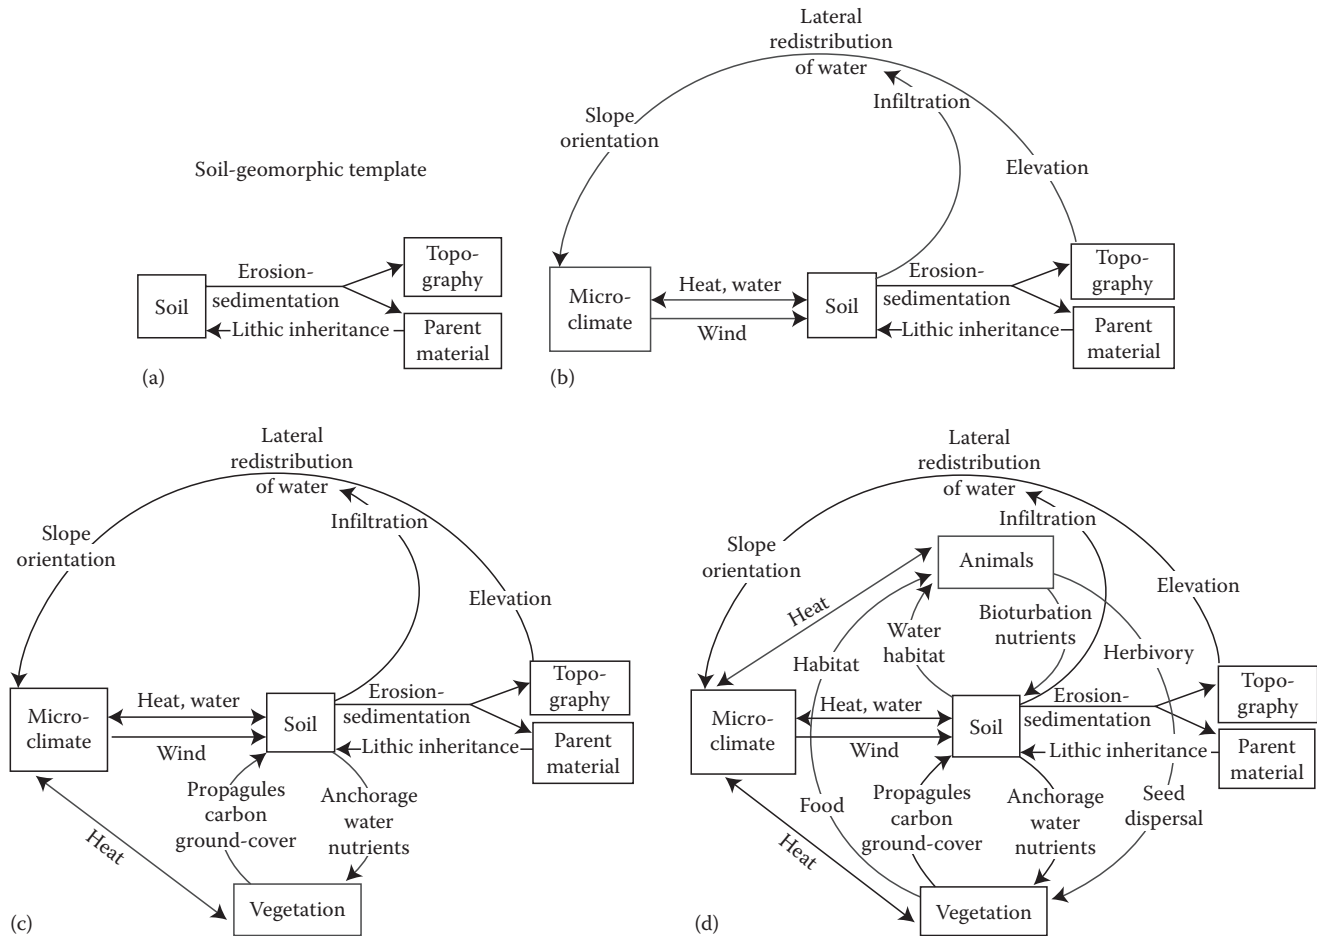
The lack of a surface outlet in closed basins precludes initial formation by water erosion. Closed basins originate through several mechanisms including deposition by ice or wind, dissolution of relatively soluble rock, subsidence due to structural failure of underlying rock often related to dissolution or groundwater fluctuations, and subsidence caused by faulting or tectonic downwarping. Closed basins are common in landscapes produced by these geomorphic processes. Examples include the "prairie potholes" and "chain lakes" of the glaciated midcontinent, depression lakes in dune topography such as the Sand Hills of Nebraska, karst topography created by dissolution of limestone, and the playa lakes of the southern Great Plains, which are partially related to wind deflation and deposition.


FIGURE 29.9 Linkages of the soil-forming factors in the soil-geomorphic template. (Modified from Monger, H.C., and B.T. Bestelmeyer. 2006. The soil-geomorphic template and biotic change in arid and semi-arid ecosystems. J. Arid Environ. 65:207–218.)

29.5.6 The Soil-Geomorphic Template

A more recent development in soil landscape models is the soil-geomorphic template introduced by Monger and Bestelmeyer (2006). It is a conceptual framework that depicts the interrelationships between the five soil-forming factors of Jenny (1941). Figure 29.9 illustrates these interrelationships. The soil-geomorphic template is defined as "…the soil, topography, and soil parent material" occurring on the landscape as a predictable pattern, which is reflected by the biotic community. Thus, it centers around the connection between topography and soil substrate on the one hand and ecological communities on the other. As such, it offers a framework to integrate various, often separated, disciplines to understand soil-geomorphic and ecological change across both short-term (centuries) and long-term (geologic) timescales.

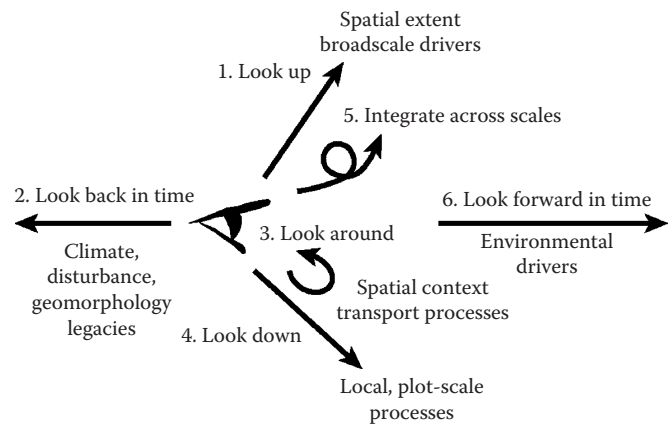
The soil-geomorphic template has been incorporated in a proposed systematic procedure that can be used to unravel the complexity of landscapes (Peters et al., 2006; Figure 29.10). In this procedure, the researcher first identifies variation in the broad-scale environmental drivers and determines the spatial extent over which these drivers influence patterns on the landscape. Historical legacies are, then, identified and connections are made between these legacies and current landscape patterns.


FIGURE 29.10 Six-step procedure to unravel landscape complexity. (Modified from Peters, D.P.C., B.T. Bestelmeyer, J.E. Herrick, E.L. Fredrickson, H.C. Monger, and K.M. Havstad. 2006. Disentangling complex landscapes: New insights into arid and semiarid system dynamics. Bioscience 56:491–501.)

Next, meso- and fine-scale spatial properties of the landscape units and the specific drivers connecting these units are identified. The information is integrated and key drivers and properties are identified at each spatial scale. Last, future effects from hypothesized changes in drivers and feedbacks are predicted.

29.6 Soil Hydrology

A major advancement in understanding soil systems has occurred in the last 20 years through insight into how water moves through landscapes: where the water goes, so goes soil development. Historically, the study of water flow in soils emphasized either overland flow, erosion, and sedimentation, or water movement within a pedon. Erosion and sedimentation control were foci of national soil programs and an integral part of agronomic applications of soil science. Efforts to understand and quantify water flow within a pedon or within fields (artificially delimited management areas versus naturally delimited bodies), such as for irrigation, have been an integral part of soil physics studies for over a century. However, water movement has not been pervasively integrated into the study of soil landscapes. To understand natural soil systems and thereby ecosystem behavior, conceptual and quantitative water-movement models must encompass water flow through soils, the vadose zone, and across and through landscapes.

Milne's concept of the catena (Milne 1936a, 1936b) recognized the existence of soils with different drainage classes across landscapes. His recognition of lateral transport as a contributing factor to landscape evolution has been de-emphasized over time. The main focus shifted to relatively static soil water conditions and vertical water flow (deep percolation) at a given position, hillslope or landscape position. Lateral transport was primarily recognized as overland flow with concomitant sediment sorting across the surface (Walker et al., 1966; Ruhe, 1975). The equally important processes of subsurface water flow and transport through soil landscapes were substantially ignored or forgotten. Soil hydrology studies in the last 20 years have expanded the catena concept to include water flow through landscapes (Arndt and Richardson, 1989; Steinwand and Fenton, 1995). There has been a simultaneous recovery from the historical emphasis on soil erosion caused by overland flow. The study of soil systems now includes the dynamic flow of water through as well as across soil and landscapes (Figure 29.11). This approach of dynamic water flow considers the entire vadose zone, not just the ground surface or the solum.

A variety of soil hydrologic terms have been developed or adopted, which partition water flow in soil systems. The terms can be placed in an idealized schematic to demonstrate relationships (Figure 29.12). These terms portray the potential fate of precipitation onto, into, and through soils. The emphasis is on water at or above the permanent groundwater table (i.e., the vadose zone). Water dynamics and aquifer conditions below the water table generally are the purview of groundwater hydrology. Water flow can be predominantly downward, lateral, or upward toward the ground surface, depending upon prevailing energy dynamics. This can be demonstrated by looking at prevailing water movement patterns in different climatic settings.
FIGURE 29.11 Three-dimensional hillslope with flow directions.
FIGURE 29.12 Soil hydrologic cycle with terminology.

29.6.1 Climate Influence

Regional climate conditions control precipitation levels and patterns and evapotranspiration dynamics (either directly via solar radiation or indirectly through vegetation populations). All else being equal, regional climate determines the dominant water flow direction through the vadose zone. Within a given temperature range, precipitation levels can vary with predictable, generalized results. In humid environments, water tables and flow paths tend to loosely mimic the local topography with water generally infiltrating (i.e., *recharge*) in topographically high areas, flowing to and discharging from lower-lying areas (Figure 29.13a). In arid to semiarid environments, conditions are reversed, with recharge sites dominantly in

low areas and subsurface water moving to and "discharging" from higher elevation areas (Figure 29.13b). Semiarid to subhumid environments behave as tension or transition zones between these two extremes. These transition zones temporarily follow either pattern depending upon short-term climatic conditions (e.g., seasonal climatic variations or annual cycles; Figure 29.13c).

Temperature also exerts a controlling climatic influence on soil hydrologic behavior both permanently and ephemerally. For example, permafrost effectively limits or precludes vertical water flow. If local conditions warm (human-induced or natural), permafrost melts and ceases to be a restriction to water flow. A seasonally ephemeral example occurs in areas that experience annual ground frost. The internal water flow behavior in soil is vastly different between winter, spring thaw, and summer (Emerson et al., 1990). Ground frost when present is an effective barrier to both

subsurface water flow and the infiltration of surface water. During several weeks in the spring, thawed soil layers immediately above a remnant frost layer can become saturated and highly erosive (e.g., Willamette Valley, Oregon). After the soil completely thaws, subsurface flow is greatly enhanced and the surface layer is no longer saturated. The transport and fate of contaminants can be radically different depending upon seasonal soil conditions. This is the basis for discouraging land application of manure on frozen soil.

29.6.2 Geostratigraphic Influence

Water restrictive (aquitard) or conductive (aquifer) sediments or rock strata can fundamentally alter subsurface water flow patterns. Tilted rock strata can preferentially redirect water such that infiltration in one location is shunted (laterally displaced) to an unlikely recharge or discharge site. Where bedrock strata approach or breach the ground surface, the vertical movement of subsurface water can be restricted, forcing water to flow back to the surface (i.e., *reflow*; Figure 29.12) and to form a spring, seep, or moist area. The composition of subsurface stratigraphic sequences and the extent to which they are connected to conductive materials also influence subsurface water flow. For example, a porous strata that is normally conductive will be nonconductive, if no outlets to other conductive material are available (e.g., a sand layer in a floodplain deposit confined by clay sediments; Figure 29.14). Similarly, a topographic position that precludes or minimizes water inputs may cause a strata that is normally conductive to be nonconductive.

29.6.3 Pedostratigraphic Influence

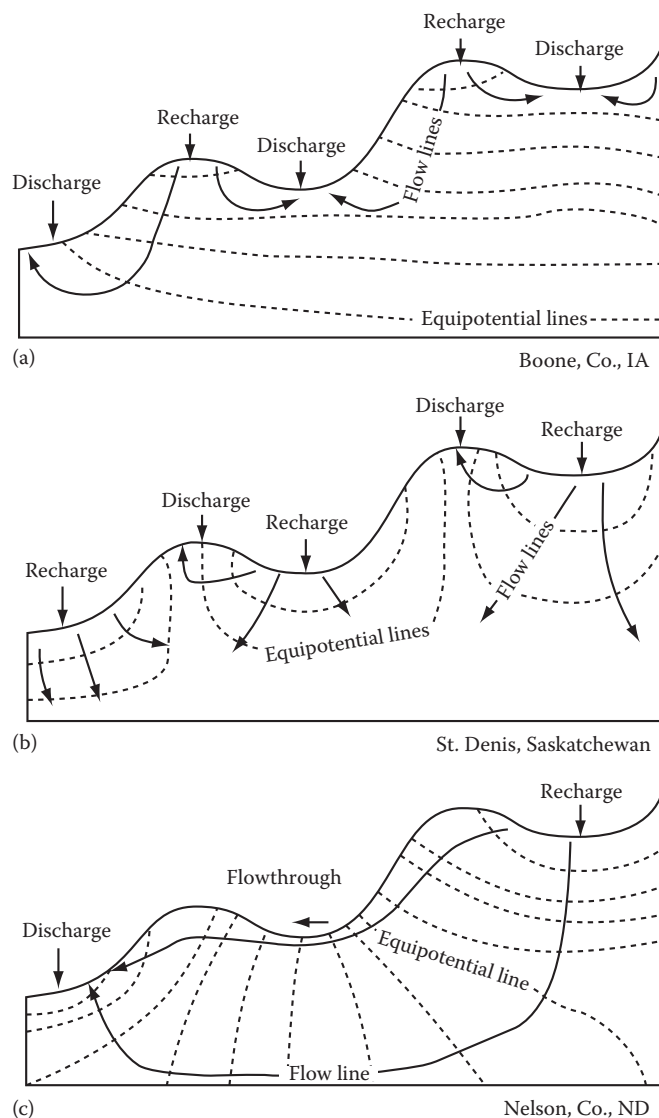
Some features unique to soil or derived from soil processes emulate geostratigraphic influences on water flow. Some pedologically derived layers such as an argillic layer (Schoeneberger et al., 1995), or duripan can restrict vertical water flow and enhance lateral flow (Figure 29.15). Water-repellent materials or layers (e.g., fire-induced hydrophobic layer in chaparral) can reduce infiltration of water into the soil or function as an aquitard and restrict vertical movement. Other pedogenic features or related phenomena such as pedogenic structure and biotic activity can greatly enhance water flow in upper soil horizons (Schoeneberger and Wysocki, 1996). Substantial differences in infiltration or internal water


FIGURE 29.13 Two-dimensional landscape diagrams with recharge–discharge, flow lines, and equipotential lines in different climatic settings (a) humid, (b) arid to remiarid, (c) remiarid to subhumid.

Eppes. 2007. Landscape dynamics fostering the development and persistence of long-lived creosote bush (*Larrea tridentata*) clones in the Mojave Desert. J. Arid Environ. 69:96–126. With permission from Academic Press.)

movement in a soil can result directly from different management practices (Franks et al., 1993, 1995).

29.6.4 Vegetative Pumping

Biotic activities, particularly plant respiration, can directly impact water flow patterns in soils. Plant communities can consume substantial volumes of water during transpiration. Water consumption may be sufficient to change local flow dynamics. Consider the case of phreatophytes fringing a marshes or riparian system (Figure 29.16). Minor differences in elevation (e.g., 10 cm) can promote plant establishment resulting in a disproportionately large reduction in water table, and subsequent differences in soils (e.g., the soil drainage class).

29.6.5 The "Soil Sponge"

An important but often overlooked function of soil is its role as a hydrologic "sponge." The porous character of soil allows
FIGURE 29.16   Diagram of vegetative pumping. (Drawn after Arndt and Richardson, 1989.)

much of the local precipitation to infiltrate. Obviously, the rate of water flow through the porous media of soil is less than that above ground. Infiltrated water is gradually transmitted vertically to recharge groundwater or laterally to be released as discharge to surface waters via throughflow. The hydrologic result is a delayed and dampened streamflow hydrograph. The importance of streamflow response can be seen from a practical, human perspective. The streamflow response for areas from which substantial amounts of soil are removed or sealed over (e.g., construction sites in urban areas) typically results in much higher and quicker peak flow compared to original conditions. This pattern can have a profound financial impact if structures are underdesigned (culverts, bridges, etc.) or if the new hydrologic dynamics initiates a new cycle of stream incisement or substantial change in sedimentation patterns (Hammer, 1995).

29.6.6 Soil Morphology, Landscapes, and Water

Water is the dominant catalyst, mediator, and transport agent in most natural systems on earth. This is true for soils. Flora, fauna, and geologic substrate all affect soil and landscape development; water, however, is the controlling force providing both chemical and potential energy. The presence and flow of water in a landscape can be observed directly by excavation or piezometers. This is a tedious and time-consuming task given the seasonal or transient presence of water. The presence of saturated conditions and the movement of water in landscapes can be predicted from soil morphology (e.g., redoximorphic features). Soil morphology forms in response to long-term prevailing water state conditions. Soil patterns on a landscape result from differing water conditions and the prevailing water flow dynamics. Soil patterns on landscapes can explain where the water is and how it flows through landscapes. Soil morphology and soilscape models can explain and/or predict soil water dynamics and subsequent soil geography.

29.6.7 Eolian Influences

In addition to, or in lieu of water, wind can serve as a dominant mediator or transport agent on landscapes. Eolian processes directly affect soils and landscapes through the addition, redistribution, or loss of clastic materials, soil nutrients, carbonates, and soluble salts. The wind-blown sediments entrained through eolian processes can significantly alter soils and landscapes from individual landforms to entire regions. The effects of these sediments vary depending upon (among other factors) climate and localized landform characteristics and include the following: supplying essential nutrients to plants, influencing the character of near-surface horizons that directly affect surface hydrology, providing materials necessary for the development of certain morphologic horizons, and providing the parent material in which thick, well-developed soils have formed (Simonson, 1995). Examples of landscapes that are dominantly affected by eolian processes are those in which soils have developed in thick loess mantles, areas inundated with volcanic ash, dune systems, and

regions with arid and semiarid climates. The impacts of loess, volcanic ash, and eolian sand (dunes) are generally geomorphically recognized. The influence of dust is less recognizable.

29.6.8 Arid and Semiarid Dust

Two profound ways in which dust can affect soil landscapes in arid and semiarid areas are as follows: the evolution of accretionary desert pavements and the formation of coppice dunes. Desert pavements are naturally occurring surficial features that consist of closely packed coarse gravel to cobble-sized rock fragments embedded into the underlying soil (Wood et al., 2005). These surfaces are often associated with silt-enriched horizons containing vesicular pores that directly underlie these pavements. Vesicular horizons are important because they significantly decrease infiltration rates into soils of these landforms thereby influencing the redistribution of water on these landscapes (Wells et al., 1985; Young et al., 2004). Desert pavements are the complex result of cumulic soil development whereby eolian fines are trapped by the surface, moved between peds into the soil, and into ped interiors through lateral conduits (Anderson et al., 2002). Both the surface armoring of the pavement and the low infiltration rate of the vesicular horizon limit the effective moisture in soils capped by desert pavement resulting in abundant quantities of near-surface nitrates and other soluble salts (Wood et al., 2005; Graham et al., 2008).

Coppice dunes form as a result of the trapping of entrained eolian silts and fine sands by shrubs. In the southwestern United States, these shrubs are commonly mesquite (*Prosopis pubescens*), greasewood (*Sarcobatus vermiculatus*), creosote bush (*Larrea tridentata*), or saltbush (*Atriplex* spp.) (Stuart et al., 1971; Rango et al., 2000; McAuliffe et al., 2007). Figure 29.17 illustrates the formation of coppice dunes. These dunes codevelop with the vegetation as the deposition of coarse silt and fine sand increases infiltration rates and enhances plant–water relationships. The dunes also provide ideal sites for burrowing fauna due to the lack
of stones, abundant coarse material, and shading by the shrub. The burrowing activity further increases water infiltration into these areas. As plant-available water is increased in these areas, shrub survival and growth is enhanced so that more sediment is trapped causing the dune to further enlarge.

29.7 Geomorphic Description of Landscapes

29.7.1 Hillslopes

Soil patterns or sequences on hillslopes will in general follow a catenary relationship. The soil and landscape relationship inherent in the catena can be used to predict and describe soil occurrence. A fairly simple set of geometric or morphometric descriptors can be used to define hillslopes and therefore associated soil patterns. These descriptors include slope gradient, slope aspect, slope shape, slope complexity, slope position, and geomorphic component (position).

29.7.2 Slope Gradient

Slope gradient, which is measured along the vertical profile of a slope, is the angle of inclination of the ground surface from the horizontal plane. Commonly, slope gradient is expressed in degrees from the horizontal plane (e.g., 45°) or as a percent, which for a 45° slope is one unit of drop or rise per one unit of distance (slope gradient equals 100%). Slope gradient is a proxy measure of potential energy that drives mass movements and the erosive force of surface runoff on a slope.

Soil map units in a soil survey include a typical range for the slope gradient (e.g., Chemawa loam, 8%–15% slopes; Van Wambeke and Forbes, 1986). Inflection points or changes in slope gradient that repeat on a landscape are readily discernible and generally correspond to differences in the internal structure (underlying lithology), past erosion events (stream incision), or contacts between landforms or sediment bodies (Figure 29.18). Inflection points on slopes, therefore, often mark natural boundaries between soils. Soil surveyors use slope inflections as visible clues to changes in soils on landscapes.

FIGURE 29.17 Diagram illustrating linkages in the codevelopment of creosote bush and coppice dunes in the Mojave Desert. (Redrawn from McAuliffe, J.R., E.P. Hamerlynck, and M.C. Eppes. 2007. Landscape dynamics fostering the development and persistence of long-lived creosote bush (*Larrea tridentata*) clones in the Mojave Desert. J. Arid Environ. 69:96–126.)
FIGURE 29.18 Diagram of natural landscape boundaries.

29.7.3 Slope Aspect

Aspect is the direction that a slope faces. Slope aspect is usually expressed as a compass azimuth (e.g., 215°) or as a cardinal direction (e.g., SW). Soil microclimates are strongly influenced by the amount of direct solar radiation, which is a function of slope aspect. In the northern hemisphere, north- and east-facing slopes are cooler and moister than south and west facing slopes. Distinct differences in soils occur as a result of aspect (Lotspeich and Smith, 1953; Finney et al., 1962; Franzmeier et al., 1969). The effects of slope aspect are more pronounced in mountainous or high-relief terrain than in low-relief areas. The influence of slope aspect is also more pronounced in temperate latitudes than in equatorial latitudes (Buol et al., 1989).

29.7.4 Slope Shape

Slope shape is the 3D geometry of a slope. The geometric form is obtained by combining the shapes of both the vertical profile (up and downslope) and the elevation contours (across slope). A 2D shape is either linear or curved. If curved, the shape can be convex or concave. This yields nine possible geometric forms to describe all slopes (Figure 29.19).

Slope shape is a property of hillslopes that strongly influences the movement of water both as overland flow and throughflow. For example, a slope that is linear in both vertical profile and contour shape creates parallel, lateral flow (Figure 29.19a). A slope that is convex in both profile and contour causes divergent flow (Figure 29.19d), and a slope concave in both profile and contour causes convergent flow (Figure 29.19h). Slope shape redistributes moisture received by precipitation, creating distinct microenvironments on the landscape. Areas of convergent flow are moister than the local climate whereas areas of divergent flow are dryer than the local climate. The influences of slope shape on water movement and soil moisture on landscapes in turn controls soil formation and vegetation.

In addition to its role in the redistribution of runoff, slope shape is a visual clue to the internal structure of a hillslope. Hillslopes that have a steeply convex, vertical profile are inherently resistant to erosion. Convex slopes occur predominately in landscapes where erosion is controlled by resistant bedrock. Soils on these slopes are shallow and usually display limited horizon development. In contrast, linear or concave slopes generally occur on unconsolidated material or weakly resistant rocks. Soils on these slopes are thicker and display greater horizon development.

Concave slopes or concave portions of slopes denote a decrease in slope gradient. Both potential energy and the velocity of overland flow decease at the inflection of a concave slope. An accumulation of colluvium or sediment derived from slope wash often occurs on concave slopes. Soils on these slopes often form by cumulic processes and usually have thick, poorly developed horizons compared to soils on adjacent uplands.

29.7.5 Slope Complexity

Slope complexity is a simplistic description of the ground surface in respect to the downslope path encountered by overland flow (Figure 29.20). Simple slopes are relatively smooth, with few obstructions to surface flow or decreases in slope gradient and thus nominal opportunities for sediment deposition. Complex slopes contain substantial irregularities in slope conditions.

(a)

(b)
FIGURE 29.20 Two-dimensional diagram of simple versus complex slopes.

FIGURE 29.19 Three-dimensional diagram of the nine hillslopes shapes with flow lines shown: L = linear, V = convex, C = concave. (Schoeneberger and Wysocki, 1997).

Surface water flow is apt to be interrupted and largely nonparallel with considerable changes in flow velocity and subsequent erosion and sediment transport capacity.

29.7.6 Slope Position

Slopes can be divided into segments or elements along a 2D, cross-sectional profile based on slope shape, the degree of erosion or deposition, the presence or absence of sediment, and the nature of the sediment. Wood (1942) identified four segments across a "fully developed slope" for a bedrock-controlled landscape. These elements are the waxing slope, free face, debris slope, and pediment. King (1957) elaborated on the geomorphic processes active on these four slope elements. The waxing slope is the convex crest of a hillslope dominated by chemical weathering rather than erosional removal. The free face is an outcrop of bare bedrock on the upper reach of a hill. Erosion is most active on this element. The debris slope occurs below the free face and is composed of material eroded and transported from the free face. Below the debris slope is the pediment, which is an inclined ramp extending from the hillslope base to an alluvial basin.

Ruhe (1960) modified Wood's 2D hillslope elements and applied them to the study of soil landscapes. Ruhe's hillslope profile elements include the summit, shoulder, backslope, footslope, and toeslope. These elements can be distinguished by inflections in slope gradient and line-segment shape (Figure 29.20). The *summit* is the relatively level, uppermost portion of a hillslope profile. It is the most geomorphically stable and least erosive part of a hillslope. The main vector of water flow is downward through the soil and erosional transport is minimal. Soils in this position display the greatest degree of profile development. The *shoulder* is the convex portion of the hillslope below the summit. The break between summit and shoulder is identified by an increase in slope gradient. The shoulder is subject to a greater degree of erosion, and greater lateral flow of water compared to the summit. Soils tend to be similar to, but thinner than those on the summit, and may appear to be vertically compressed or truncated. The shoulder descends to the steepest and more linear portion of the slope, the *backslope*, where surface runoff and erosional transport are greatest. The vector of water flow may be more lateral than vertical depending on the slope gradient. Soils may reflect inputs of less weathered parent material than soils on the summit and shoulder. On long slopes some degree of lateral sorting may be evident. The backslope descends to the concave portion of a hillslope, the *footslope*. The decrease in slope gradient reduces the carrying capacity of flowing water and increases sediment accumulation. Water flow vectors may be primarily lateral, but the position is characterized by the concentration of water from upslope. The footslope merges downslope with the *toeslope*. The toeslope is predominantly linear or slightly concave. The comparatively low slope gradient and low-lying position at the toeslope allows alluvial processes to dominate, given sufficient surface water from upslope or adjacent streams.

Soils tend to be deep, comparatively moist, and composed of or strongly influenced by alluvial sediments. Toeslope sediments from lower order streams reflect short distance transport and a lower degree of fluvial modification (sorting, rounding, stratification, etc.) than toeslope sediments derived from higher order streams.

29.8 Geomorphic Components

A major focus of soil geomorphology is the movement of water through soil bodies and the way that a landscape sheds or concentrates water (surface flow). This focus is the result of the impact of surficial fluvial processes on major agricultural areas and population centers. Consequently, terms have evolved to describe portions of the earth's surface that share a common location, form, and geomorphic process and the practical emphasis on surficial water movement.

In addition to the 2D hillslope elements (Figures 29.20 and 29.21; Ruhe, 1960), Ruhe refined and popularized geomorphic descriptors for 3D pieces of landforms (Ruhe, 1969, 1975). These area descriptors, called *geomorphic components*, are based in part upon the convergent, linear (or parallel), or divergent nature of overland water flow (Figure 29.19) and associated sediment transport. The most widely used suite of geomorphic components was developed for and is most appropriately applied to hills. Historically, this set of terms has been applied to most landscapes, including mountains, due more to the lack of alternatives than to their utility. Other geomorphic settings (mountains, terraces, flat plains) have unique dynamics or complexity and warrant different area descriptors.

29.8.1 Geomorphic Components: Hills

The *interfluve* is the uppermost area of a hill, and represents the oldest, most stable part of the landscape, typically with the most developed soils. A noted exception is where opposing hillslopes have narrowed an interfluve or merged (e.g., a saddle or crest) to the extent that erosion begins to lower the crest. Hillsides are areas characterized by active backwearing (erosion) in general, and at the heads of streams in particular.

Hillsides can be divided into discrete parts (Walker and Ruhe, 1968) based on the dominant behavior of overland water
FIGURE 29.21 Hillslope profile terms and associated slope shapes.

flow (Figure 29.8a): converging (*head slope*), linear or parallel (*side slope*), or diverging flow (*nose slope*). Soils on hillsides are dominated by colluvial sediments in gradual transport down the slope and modified to varying degrees by slope wash (nonchannel, overland flow). Unless masked by changes in parent materials, some degree of lateral sorting downslope is usually present. Soil profiles on hillsides can range from thin to thick depending on the rate of erosion (high or low, respectively), the magnitude of the slope gradient, and the extent to which the bedrock is resistant to weathering and erosion. In many landscapes, the traditional assumption of a prevalence of shallow soils over hard rock on hillsides and mountainsides is erroneous (Knox, 1982; Graham, 1986). The *base slope* is commonly an apron or wedge of colluvium at the bottom of hillslopes (Schoeneberger and Wysocki, 1996). This drape of transported material can range from coarse debris to finer sediments that have been winnowed or sorted by slope-wash processes. The base slope does not typically include sorted and stratified alluvium associated with channel deposition. Distal base slope sediments commonly grade into or interfinger with alluvial fills.

29.8.2 Geomorphic Components: Mountains

Mountains represent a unique geomorphic setting due to their scale and slope complexity. Mountainsides commonly have long, complex backslopes up to thousands of meters long, steep slope gradients, highly diverse sediment mantles and complex, near-surface hydrology. Mass movement processes and features are more prevalent than in hills. Consequently, new area descriptors have been developed (Schoeneberger and Wysocki, 1996; Hirmas, 2008) that effectively identify and name geomorphic components for mountains.

The *mountaintop* (Figure 29.22) is the summit or crest of a mountain and is commonly characterized by comparatively short, simple slopes composed of bare rock, residuum, or short-transport (angular) colluvial sediments. In humid climates, soils on mountaintops can be quite thick (Oliver et al., 1997), whereas in arid climates, these soils may be capped by well-developed desert pavements and accumulate considerable quantities of carbonate, nitrate, and other soluble salts (Graham et al., 2008). The side of a mountain, the *mountainflank*, is characterized by comparatively long, complex slopes dominated by mantles of long transport (subangular) colluvium. Residuum, if present, is usually buried by 1–2 m of colluvium. Incised drainageways, structural benches, and mass movement features can be common. Rock outcrops, while visually prominent, are not a major portion of the land surface. The *mountainbase* is an apron of colluvium at the bottom of a mountain slope and analogous to the *base slope* in hills. It is marked by a substantial decrease in slope gradient compared to the mountainflank. The mountainbase is characterized by a thick mantle or wedge of colluvium and commonly contains a comparatively high percentage of coarse rock fragments. The colluvium can extend out onto more level land surfaces, and ultimately interfingers with or is buried by alluvium, or thins and joins re-emergent residuum. In desert environments, windward sides of these mountainflanks and mountainbases can trap significant amounts of dust within which, thick soils may develop (Blank et al., 1996; Hirmas, 2008). Hirmas (2008) described a feedback process in these landscapes where sediment is added to lower-lying landforms through alluvial and debris-flow processes while, concurrently, material entrained from these landforms is carried back to the mountains by wind to serve as parent material for mountain soils (Figure 29.23).
FIGURE 29.22 Geomorphic components for mountain landscapes. (From Schoeneberger, P.J., and D.A. Wysocki. 1996. Geomorphic descriptors for landforms and geomorphic components: Effective models, weaknesses and gaps. (Abstract). American Society of Agronomy, Annual Meetings. ASA, Indianapolis, IN.)

Surface processes, pedology, and soil-landscape modeling of the southern Fry Mountain Bolson, Mojave Desert, California. Ph.D. Dissertation. University of California. Riverside, CA.)

29.8.3 Geomorphic Components: Terraces

Terraces are landforms that form a relatively level or gently inclined surface, a constructional strip, or plain that borders a stream, lake, or sea. Terraces are a unique geomorphic setting and have dynamics quite different from those of hills or mountains. Stream terraces and floodplain steps (Figure 29.24) are originally developed by alluvial processes and sediments, rather than the dynamic slope processes and colluvial sediments that characterize hills and mountains or the localized, low energy processes typical of flat plains.

The *tread* is the comparatively broad, generally level part of a terrace or floodplain step. Treads can extend laterally for many kilometers (Gamble, 1993; Saucier, 1994). Treads are level or gently inclined (low gradients) and underlain by alluvial, lacustrine, or marine sediments. Strath terraces are similar in form to other stream terraces, but are erosional landforms characterized by thin alluvial sediments over an eroded bedrock bench or platform.

The *riser* is an escarpment that separates terrace or floodplain levels. The riser commonly consists of a short, steep, planar slope cut into the sediments that underlie the adjacent tread. The areal extent of a riser rarely exceeds tens of meters and therefore is typically depicted on a soil map with a spot symbol rather than a delineation. Geomorphically, risers represent an abrupt change to a lower hydrologic base level, which suppresses the water table along the edge of the adjacent, higher surface. This directly affects soil processes and subsequent soil geography. Soils above and adjacent to a riser tend to be better drained than those farther away from the escarpment (Figure 29.25). Daniels and Gamble, 1967 called this relationship the "red edge effect." Soils at the base of a riser tend to be as wet as or wetter than those farther from the scarp. This is especially true in floodplains.
FIGURE 29.24 Geomorphic components for terraces and floodplains.
FIGURE 29.25 Two-dimensional landscape diagram showing drainage relationships on low-relief divides.

29.8.4 Stream Terraces versus Floodplain Steps

Fluvial landforms include the active channel, surfaces that are intermittently inundated, and higher areas that no longer flood or receive alluvial sediments. The distinction between stream terraces and floodplain steps is an arbitrary break in a natural continuum. There are practical pedological reasons for separating areas that are within the active floodplain from areas that flood or receive sediments in rare instances. For most land uses (e.g., home site), it is valuable to know the relative occurrence of flooding. Terraces are defined as a part of the fluvial system that no longer actively experiences fluvial modification (Ruhe, 1975), that is, no longer aggrading (receiving additional alluvial sediments), no longer experience significant flooding. Floodplain steps are morphometrically similar to terraces, except that they occur within the fluvially active portion of a floodplain and are subject to relatively frequent modification (experience relatively regular or significant flooding and alluvial sediment inputs). Pedologically, terraces commonly have more extensively developed soils (e.g., alfisols, ultisols) compared to lesser-developed soils (e.g., inceptisols, entisols) of floodplain steps. The practical separation of terraces from floodplain steps varies. Stream terraces that have not flooded during recorded history could be inundated during rare, catastrophic events (e.g., 500 year flood). Soil development on terraces is usually controlled more by moisture derived from precipitation than from the adjacent river. Terrace soils in cold or dry climates, despite a greater age and lack of new sediment, may closely resemble soils on adjacent floodplain steps that periodically receive fresh sediment. Conversely, soils on floodplain steps in hot, humid settings may exhibit extensive development and resemble soils on the older, adjacent terraces. In temperate North America, a practical separation between terraces and floodplain steps (Figure 29.24) is the 100 year flood stage (Soil Survey Staff, 1998).

29.8.5 Geomorphic Components: Flat Plains

Broad, flat plains such as proglacial lake plains, low-lying coastal plains, and low-gradient glacial till plains are a geomorphic setting distinct from hills, mountains, or terraces. The primary differences are geomorphic origin (nonfluvial) and the low potential energy to drive water flow. Historically, generic terms (e.g., flat, broad interstream divide, rise) or terms developed for other settings have been applied to flat plains with unsatisfactory results. Recent interest and recognized value of wetlands and hydric soils (e.g., Mausbach and Richardson, 1994) highlights the need for unique descriptors for flat areas. Small differences in elevation (e.g., 15 cm or less) on a landscape can mark the change from moderately well drained to very poorly drained soils (Richardson, 1997). The search is presently on for better, unique descriptors to express the geomorphic components of flat plains. The following terms are proposed as provisional contenders.

Flat plains are subdued landscapes dominated by broad areas with low slope gradients (e.g., 0%–1%) called *talfs* (Figure 29.26), and closed depressions, with only nominal changes in local relief (i.e., microhighs, microlows). A *rise* is a slightly elevated area (i.e., microhigh), which tends to be broad with low slope gradients (e.g., 1%–3%). The low gradients of flat plains result in minimal erosion by running water, especially if vegetated. Consequently, fluvial drainage networks tend to be poorly developed: nonintegrated, incipient, or deranged. Precipitation tends to pond locally and lateral transport is slow both above and below ground. These conditions favor accumulation of organic matter (e.g., pocosins, upland bogs) and retention of water and fine earth (<2 mm diameter) sediments.

29.8.6 Microrelief

As used here, microrelief refers to slight variations in the height of a land surface that are too small to delineate on a
- Very low gradients (e.g., slope 0%–1%)

- Deranged, non integrated, or incipient drainage network

- "High areas" are broad and low (e.g., slope 1%–3%)

- Sediments commonly lacustrine, alluvial, or till

FIGURE 29.26   Geomorphic components for flat low-relief plains.

topographic or soils map at commonly used scales (e.g., 1:24,000 and 1:10,000). Examples of microrelief include microhighs and microlows. These minor elevational differences can have a surprisingly large impact on vegetation distribution, soil hydrologic dynamics (Hopkins, 1996), and sedimentation patterns. This approach to microrelief is strictly morphometric. We make a distinction between small elevational differences (*microrelief*) and small features (*microfeature*) with which these elevational differences are associated. An example is gilgai (a kind of microfeature), with the associated microrelief (mound areas = microhighs, bowl areas = microlows). It is an unfortunate yet common practice to confuse the two items and describe both as "microrelief."

29.9 Landscapes, Landforms, Microfeatures, and Anthropogenic Features

Armed with the ability to describe the most detailed morphometric nuances of the land surface, one is inevitably faced with some variation of the question: "Taken all together, what is this feature that we see and what should it be called?" A potpourri of names has been applied over time that connotes internal composition, form, arrangement, collective relationships, and origin. These terms range in scale from small, human scale features to continental-scale assemblages. Confronted with such complexity, some organization of terminology is reasonable and in fact, necessary. Various schema have been developed to achieve this, typically from a particular geographical perspective: Developed schema include physiography (Fenneman, 1931, 1938, 1946; Thornbury, 1965, 1969; Hunt, 1967), landuse (USDA-SCS, 1981), and ecology (Omernik, 1987, 1995; Bailey et al., 1994; USDA-EPA, 1996). A different approach is to de-emphasize the geographical context and focus on geomorphic

process (Peterson, 1981). One pseudohierarchy of terms has been assembled specifically from and for soil survey and geographic applications (Schoeneberger and Wysocki, 1997). In addition to morphometric terminology and physiographic location, this system loosely arrays land surface features in a progression of scale in the following fashion.

A *microfeature* is a small, local, natural form (feature) on the land surface that is too small to delineate on a topographic or soils map at commonly used map scales (e.g., 1:24,000 to 1:10,000). *Note*: The conventional use of microrelief commonly encompasses some of the terms or features that in this system are contained within microfeature (see below).

A *landform* is any physical, recognizable form or feature on the earth's surface, having a characteristic shape and range in composition, and produced by natural causes; it can span a wide range in size (e.g., *dune* encompass both *parabolic dune*, which can be several tens-of-meters across, as well as *seif dune*, which can be up to 100 km long). Landforms provide an empirical description of similar portions of the earth's surface.

A *landscape* is a collection of spatially related, natural landforms, usually the collective land surface that the eye can comprehend in a single view (Soil Survey Staff, 1998).

An *anthropogenic feature* is an artificial feature on the land surface, having a characteristic shape and range in composition, composed of unconsolidated earthy or organic materials, artificial materials, or bedrock, that is the direct result of human manipulation or activities. Historically, landforms and the like have been defined as, and therefore restricted to, natural features. There are relatively consistent formational processes with common compositional, structural, stratigraphic results within a population of natural features (e.g., sand dunes). Human-made features may have a common theme in intent (e.g., water impoundment), but can have an almost limitless variety of formational processes, material composition, and internal structure. This simplifies the study and interpretation of the land's surface but ignores human-made features, which progressively apply to ever more of the earth.

29.10 Age Assessment of Soil Landscapes

Age assessment of landscapes is the single most important contribution that geomorphology makes to the understanding of soils. The law of superposition and the concept of geomorphic surfaces are the key principles for defining relative age relationships in a landscape (Daniels et al., 1971; Hall, 1983). Radiometric, isotopic, or paleontological dating combined with field studies using geomorphic and stratigraphic principles can establish the absolute age of a deposit, soil, or a landscape.

The longer a landscape is exposed to subaerial weathering, the greater the potential for soil development. The terms "weathered," "well developed," and "old" are relative indicators of time in soil formation, but none are accurate descriptors of age. *Weathered* refers to the relative stability stage (Goldich, 1938;

Jackson, 1968) of the minerals contained in a soil. The *weathering stage* is a function of age, weathering intensity, and mineral stage of the parent material. A chronologically young soil may be composed of highly weathered minerals if the parent material is preweathered.

Development is a relative measure of soil formation based on the type and degree of horizonation. Soil development is a function of both age and the rate of horizon formation. Rate of horizon formation depends on the intensity of soil-forming processes (see Chapter 30) and composition and resistance of the parent material to change. Soils of similar morphology can differ substantially in age. For example, Burges and Drover (1953) reported that spodic horizons in Australia formed in sandy beach deposits within 1000–3000 years. Franzmeier and Whiteside (1963) found that spodic horizons took 8000 years to form on dunes in northern Michigan. Holzhey et al. (1975) suggested 21,000–28,000 years for development of thick spodic horizons in North Carolina. Well-developed, weathered soils are described as *old*. In this context, *old* is a proxy for age based on weathering and degree of soil formation. Geomorphic principles are a means to assess soil and landscape age independent of horizon development or weathering stage.

The law of superposition specifies the sequence of deposition of sedimentary rocks and unconsolidated sedimentary deposits. Sediment can only be deposited atop preexisting materials. Younger beds or strata invariably overlie older beds, if not overturned. Bed 2 (Figure 29.27a) is younger than Bed 1. Once deposition ceases, the top of Bed 2 represents a depositional surface (surface A) equal in age to the youngest strata in the bed. Stabilization of the surface allows a soil to form in the sediment (Figure 29.27b). This is time zero for subaerial weathering and soil formation. The surface and soil age are the same. The passage of time is recorded by an increasing degree of soil development. Soil formation requires a period of nondeposition and therefore indicates an unconformity in the sedimentary sequence. A buried

soil represents an unconformity in the sedimentary sequence. For example, deposition of Bed 3 buries the older units and the soil formed on them (Figure 29.27c). Bed 3 is the youngest deposit. The top of Bed 3 is a new, younger depositional surface B. The stratigraphic record contains three depositional beds and a buried soil.

29.10.1 Geomorphic Surfaces

In a landscape, an erosion cycle or event (e.g., stream incision, hillslope retreat, pedimentation) that cuts existing beds creates a geomorphic surface of erosional origin (Figure 29.28). This erosion surface is younger than any strata, soil, or surface that it cuts. An erosional surface can only cut preexisting materials, strata, or surfaces. As you ascend a landscape geomorphic surfaces increase in age. This is the principle of ascendancy. Surface E1 is younger than surface A and younger than beds 1, 2, and 3. The cutting of an erosional surface produces sediment that is deposited downslope or down valley. The erosional surface descends or grades to a corresponding depositional surface and the underlying alluvium (Figure 29.28). The depositional

(a)

(b)

(a)   (b)

(c)

FIGURE 29.27 Three-dimensional block diagram depicting the law of superposition.
FIGURE 29.29   Three-dimensional block diagram showing geomorphic surfaces and dating of sediments.

and erosional surfaces and the top of the alluvium are all the same age. An erosional surface is the same age as the alluvium to which it descends. This is the principle of descendancy. Relative age of an erosional surface in the field can be determined by observing what it slopes downward to in a smooth, concave profile (Daniels et al., 1971).

29.10.2 Stepped Surfaces

Landscape evolution commonly proceeds episodically through time, which creates a series of stepped or faceted geomorphic surfaces along interfluves (Ruhe et al., 1968; Gamble, 1993; Figure 29.29). The age relationships of stepped surfaces follow the principles of ascendancy and descendancy. Surface A on the interfluve summit is the oldest, surfaces become successively younger as you descend the landscape. The age differences between surfaces depend on the timing of the erosional processes that produced them.

29.10.3 Absolute Age Assessment

Dating techniques along with the geomorphic relationships provide a framework for establishing a landscape chronology. For example, ages shown in Figure 29.29, which could be obtained by C14, luminescence techniques, or fossil analysis, establish the periods for deposition. Surface D is underlain by sediment with an age of 5 ka at the base. This unit is inset into an alluvium that has an age of 15 ka at the base and 10 ka near the top. Stream incision and back filling therefore occurred between 5 and 10 ka that deposited the alluvium under surface D. Surface C includes both an erosional depositional element. Cutting of the erosional surface occurred between 10 and 15 ka based on the alluvium to which it descends. The alluvium is a time transgressive deposit as is the cutting of the erosional surface. Alluvium under surface B has an age of 100 ka and the erosional element ascends to a surface of 250 ka. The erosional processes that created surface B began later than 250 ka and ended by 100 ka. Given this scenario, the absolute age differences between the surfaces and the soils on them can be established.

29.10.4 Geomorphic History

The concepts as displayed in Figures 29.27 through 29.29 are straightforward. Application to soil landscapes requires detailed stratigraphic control obtainable only by field observations from natural (e.g., stream banks) or man-made (e.g., road embankments) exposures or drill cores and the ability to think in three dimensions. The geomorphic history of a region must sometimes be established through detailed stratigraphic investigation before soil patterns are completely understood (Ruhe et al., 1967; Daniels et al., 1970).

Consider the geomorphic history of a hypothetical landscape in Figure 29.30. A landscape is composed of soil s1 on geomorphic surface A, which is formed in a single deposit (Figure 29.30a). The deposit is buried by a younger material (e.g., alluvium, glacial till, loess) with subsequent development of soil s2 on surface B (Figure 29.30b). The landscape now consists of two stacked stratigraphic units separated by a buried soil s1. Stream incision cuts an erosion surface across both units (Figure 29.30c). The landscape becomes a two stepped sequence comprising surfaces B and C. Soil s3 forms in surface C (Figure 29.30d). Two soils s2 and s3 of different age make up the landscape. Valley alluviation buries surface C and reduces relief in the landscape (Figure 29.30e). Soil s4 forms in surface D on the alluvium (Figure 29.30f). The soil landscape at this point consists of two soils s2 and s4, which again differ considerably in age. Stream incision and back filling inset a deposit into the preexisting alluvium (Figure 29.30g). The inset is denoted by surface E and soil s5. The landscape now includes three surface soils s2, s4, and s5, all of different age. Soil distribution on the landscape, soil age, and the geomorphic history of this landscape can only be established from multiple field observations and drill cores at critical locations that identify all the stratigraphic units and buried soils.

29.10.5 Soils and Geomorphic Surfaces

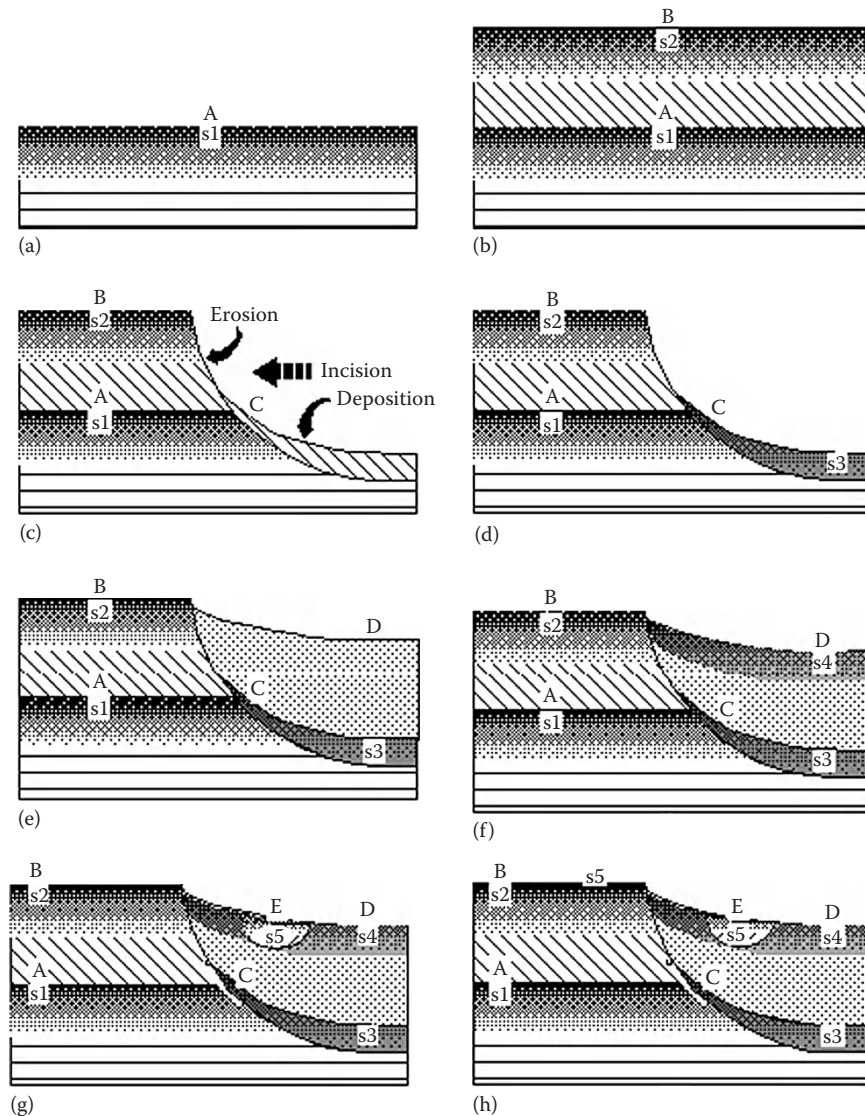
Despite the strong association between soils and geomorphic surfaces, soil patterns and morphology cannot be used to initially define or recognize geomorphic surfaces. Geomorphic surfaces must first be defined using geomorphic principles


FIGURE 29.30 Two-dimensional diagram explaining hypothetical landscape evolution.

and then the linkages made to soil patterns. A soil or suites of soils may occur on more than one geomorphic surface and soil boundaries do not always correspond to geomorphic boundaries on a landscape. Consider Figure 29.31, which shows a stratigraphic sequence and soil horizons cut by an erosional surface. Soils 2, 3, and 4 on erosional surface B form over beds of varying composition and age and from preexisting soil horizons. Soils 2, 3, and 4, however, are all the same age (the age of surface B). In this case, three different soils occur on the erosional surface. The sequence of soils is determined by the stratigraphic units present and erosional sorting along the surface. The same erosional surface across its geographic occurrence can cut different strata or sediments. The soils in that case would differ.

The boundary between soil 1 and soil 2 (Figure 29.31c) lies below the slope break that denotes the erosional surface. Erosion has not removed enough of the original profile to cause a change

in the soil. The boundary between the surfaces and the boundary between soils are not coincident. A soil map and a geomorphic surface of the same landscape would not have coincident boundaries.

29.11 Paleosols, Geosols, and Climate Interpretation

29.11.1 Paleosols

Geologic processes that create and destroy soils and landscapes vary in time and space. Continental-scale processes like glaciation can create or destroy entire landscapes. More commonly landscapes evolve by erosion and deposition on only parts of them. Erosion removes soils and sediments from the active parts of landscapes, while soils continue to form on the stable parts. Sediment from
FIGURE 29.31   Two-dimensional diagram relating soils and geomorphic surfaces.

erosion buries preexisting surfaces, soils, and sediments. Buried soils and soils that endure on stable landscapes for long periods become part of the geologic record and are valuable for interpreting earth history. *Paleosols* are soils that formed on landscapes of the past (Yaalon, 1971; Valentine and Dalrymple, 1976). Age alone, however, does not denote a paleosol. The process or processes responsible for the soil morphology must no longer operate due to a change in climate, local environment, or because of burial.

Ruhe (1965) recognized three types of paleosols buried, exhumed, and relict. *Buried paleosols* form at the land surface, but later are covered by sediment, which removes the paleosol from the dominant soil-forming zone. Burial must be deep enough to suspend the soil-forming processes, and rapid enough to prevent formation of a cumulic soil profile. Postburial and diagenetic changes in soil properties and horizons are common (Yaalon, 1971; Olson and Nettleton, 1999) and must be considered when studying paleosol composition.

Exhumed paleosols form at the land surface, are buried, and later re-exposed on younger landscapes by erosion of the covering sediment (Ruhe, 1969). Erosion exposes both the paleosol and the former land surface. Exhumed paleosols rarely contain completely intact paleosolums. Former A horizons are usually truncated or mixed with the burial sediment and difficult to recognize. In contrast, B horizons are the best preserved and most easily discerned feature of exhumed paleosols. An exhumed paleosol differs from a buried one in that the outcrop can be traced across a significant area of the present land surface. An exhumed paleosol can be out of balance with both the existing climate and the adjacent soils on the landscape. Landscapes that include exhumed paleosols may not conform to the expected catena relationship in a geographic area (Figure 29.32; Ruhe, 1969).
FIGURE 29.32   Landscape diagram showing buried and exhumed, paleosols.

Relict paleosols are soils formed on preexisting landscapes and were never buried (Ruhe, 1965). Therefore, identification of relict paleosols is somewhat problematic. A relict paleosol must have endured one or more shifts in regional climate or local environment (e.g., lowering of a water table by stream incision or baselevel change) such that it is no longer is in balance with the existing conditions. This concept requires that the age of the landscape be known or inferred and that we have a precise understanding of the processes responsible for soil morphology (see Chapter 30 for discussion). Soils on old, easily distinguishable geomorphic surfaces such as terraces (Figure 29.33) are the most commonly recognized relict paleosols.

Our present knowledge of soil processes is inadequate to determine relict versus nonrelict soil conditions in all situations.
FIGURE 29.33 Landscape diagram depicting relict paleosol.

Soil-forming processes can be reversible self-terminating, steady state or metastable, or irreversible self-terminating (Yaalon, 1971). This means that all morphological features do not have equal utility as indicators of climate change. For example, the formation of silica-cemented soil horizons, or duripans, occurs in arid or semiarid climates (Soil Survey Staff, 1996). Once formed, a duripan is resistant to destruction even in humid conditions. Thus, the presence of a duripan in a humid climate is strong evidence of a relict condition. In contrast, some morphological features such as A horizon thickness and color, which have a strong correlation to present climatic regimes, can adjust rapidly to a shift in climate. Despite the difficulties in defining and recognizing relict paleosols, this concept is valuable because it focuses on the relationships of landscape age and soil processes.

29.11.2 Geosols

Buried paleosols are integral components of the stratigraphic record. Formation of a soil requires a period of landscape stability with exposure to subaerial weathering. A buried paleosol, therefore, (1) represents an unconformity in a sedimentary sequence and (2) marks a consistent stratigraphic position at the top of a sedimentary body or bodies. Buried paleosols that are laterally traceable with 3D form and have mappable distribution at a scale of 1:24,000 can be formally defined as pedostratigraphic units (Morrison, 1967) called *geosols* (NACSN, 1983). Geosols include only pedogenic horizons formed in preexisting rock or sediment bodies. Buried O horizons and some C horizons of paleosols are excluded from geosols. A geosol may form in parent materials of diverse ages and composition. Formal naming and establishing of geosols follows the same criteria of other stratigraphic units (NACSN, 1983). A geosol is named after a geographic feature in the type area.

29.11.3 Climate Change and Paleosols

Jenny's (1941) model can be solved for an individual soil-forming factor. For example, the equation

$$\text{Soil} = f'(c)_{p,r,b,t} \qquad (29.1)$$

ascertains the climate during soil formation, where the subscripts denote a constancy in the factors of parent material, relief, biota, and time. There are problems with this approach, however, Equation 29.1 defines the soil-forming factors as independent variables, but in reality the factors covary. It is also difficult to assign quantitative values to some factors, particularly parent material and the biota. Nonetheless, this approach allows useful, semiquantitative comparisons between soil morphology and individual soil-forming factors.

Processes of soil formation occur over time scales of tens to thousands of years. Soil morphology forms a physical record of the climate, vegetation, and/or environment during the time of formation. Recent emphasis on global climate change has renewed interest in paleosols as indicators of past climates. Numerous studies have used soil morphology to interpret past climates or environments (Busacca, 1989; Driese et al., 2005; Retallack, 2005; Brock and Buck, 2009). The interpretation of climate based on paleosols requires one or more of the following: (1) that the paleosol existed on a stable landscape and had reached a steady state within a particular climate, (2) identification of the ancient soil environment (e.g., floodplain), and/or (3) identification of the catenary relationship or position of the paleosol on the ancient landscape.

For example, a climatic interpretation based solely on the properties of the Clarion profile (Figure 29.6), such as A horizon thickness, organic carbon content, depth to inorganic carbonate, and B horizon color are indicative of a well drained, prairie soil formed in the present humid climate of central Iowa. If only the Harps soil (Figure 29.6) is considered, which has a thicker, darker A horizon, a gray B horizon, and inorganic carbonates are at or near the surface, a climate more humid than the Clarion morphology is indicated. Carbonates near the surface suggest a climate more arid than Clarion and the A horizon thickness suggests a cooler climate. Despite occurring only tens of meters from Clarion soils on the landscape, the morphology of Harps soils leads to an ambiguous and a potentially erroneous interpretation of the regional climate. Climatic interpretations based on paleosol morphology must include paleocatenary relationships.

30.1 Introduction

Soil is a mixture of geological parent material, living organisms, and the colloidal residue of their interaction. The colloidal fraction is particularly important in imparting soil with its unique characteristics. The nature of soil exposes a large surface area that gives rise to adsorption of water and chemicals, ion exchange, adhesion and capillarity, swelling and shrinking, and dispersion and flocculation. Soil colloids include inorganic (clay minerals) and organic (humus) components. The nature and amount of these colloids vary in response to environmental stimuli and organic input. Their variation is responsible for lateral differentiation in soil properties. Soils are separated vertically into horizons that indicate differences in the internal soil environment, which, in turn, determines the amount and character of soil colloid accumulation. This chapter provides an overview of the way in which soil properties vary as soils develop under varying environmental stimuli.

Soil formation is powered by gradients in chemical and physical potential as Earth's atmosphere and biosphere interact with rocks and minerals. Rock minerals are formed at high temperature and pressure, which makes them susceptible to attack by water and the biospherically derived acids existing in soils. The fundamental mechanisms of physical, chemical, and biological processes in soils are discussed in Parts I, II, and IV. Here the focus will be on the matrix of processes that produce 3D soil bodies called pedons, which have differentiated horizons and lateral variability.

30.2 Environmental Factors That Drive Pedogenesis

The concept of soil-forming factors is one of the earliest and most important of soil science. It defines soil as a component of ecosystems that must be characterized in terms of both geological substrate and biological input (Jenny, 1941; Amundson and Jenny, 1997). It provides a far-reaching description of the controls on soil processes that allows prediction of general soil properties based on the interaction of a relatively small number of driving variables. In the words of Hans Jenny (1980), "Pedogenic order in a landscape is unraveled by stratified random sampling along vectors of the state factors." Knowledge of the soil properties produced by the interaction of environmental variables allows prediction of soil characteristics in detail, locally, or in general, regionally and globally. The fact that characteristics of soil properties can be predicted based on environmental variables is critical to soil resource mapping because it is impossible to observe soil profiles everywhere.

The interaction of environmental variables establishes the soil-forming processes whose actions on parent material manifest themselves in characteristic soil morphologies, which may, in turn, alter the nature of the ongoing processes. Environmental variables are broadly grouped as geological, climatological, biological, and topographical. The geological characteristics constitute a site factor that sets the initial condition for soil formation, whereas the climatological and biological factors represent energy input that drives soil development. The energy factors share a strong spatial covariance because of the dependence of organisms on climate. Within any of these groupings, local differences in topography modify the activity of the more broadly defined variables. Human manipulation of edaphic environments is significant enough to warrant close consideration of their effect on soil properties (Amundson and Jenny, 1991). Dynamic soil properties (e.g., soil organic carbon, bulk density, pH, salinity, aggregate stability) that change on timescales from decades to centuries are most affected by human land use (Tugel et al., 2005).

30.2.1 Geologic Foundation: Lithology, Mineralogy, and Topography

Geological processes ranging from plate tectonics and volcanism to deep ocean carbonate sedimentation to glaciations create conditions that eventually provide substrate for soil

development. Plate tectonics drive global processes that differentiate lighter, silica-rich rocks from the mantle into the crust and create relief that produces erosion, accumulation of alluvium, and formation of sedimentary rocks. Continental areas that are actively uplifted, such as the Tibetan plateau and the cordillera of South and North America, support thin, young soils. In contrast, those areas on stable cratons, such as central West Africa, Brazil, and Australia, have deep soils that are superimposed on thick, highly weathered saprolite zones (Paton et al., 1995). In these ancient cratons, depth to unweathered rock can exceed 100 m. Volcanism brings locally melted silica-rich rock in subduction zones to the surface in areas such as Japan, Indonesia, and Washington state. Hot spots, such as Hawaii, the Canary Islands, or Yellowstone, provide a direct conduit from mantle to surface for Fe- and Mg-rich rocks. A dramatic example of mantle-fed volcanism is exhibited by flood basalts on the Columbia and Deccan plateaus. On ocean floors, far from continental inflow, deposition of carbonate produces limestone that, when subaerially exposed, has distinct parent material properties when compared with igneous rock.

In polar and temperate zones, glacial advances deposit moraines and outwash composed of the mix of lithologies crossed by the glacier. The more finely ground glacial drift is lofted into the atmosphere and deposited as loess. Numerous Pleistocene glaciations have left distinctly younger soils than the deeply weathered soils of stable craton areas in the tropics. Even within temperate zones, there are strong differences in soil properties between recently glaciated areas and those that have not been overrun. Globally, much of the variation in soil properties can be attributed directly to differences in parent material mineralogy and the dynamics of Earth's history. Locally they are important as well. For instance, stream channel and associated hillslope erosion may cut through an extensive surficial geological unit into an underlying lithology that has different mineralogical and chemical properties, which affect soil properties of soils that form on that unit (Chapter 29).

Parent material lithology determines the physical and mineralogical nature of soil. For example, soil formed in marine clays or shale inherits a large quantity of colloids that lead to poor water infiltration, relatively low plant-available water, and substantial shrink/swell behavior. In contrast, soils formed on quartz sandstone or weathered granite are likely to be sandy with little inherited clay. Commonly, they are excessively drained and often have low fertility and water-holding capacity. Fracture patterns in the underlying bedrock provide preferential lines of water flow, which enhance weathering and soil formation. The stratigraphic juxtaposition of soft and hard lithologies provides gentler and steeper relief and less or more rock fragments in the overlying soil.

Parent material mineralogy determines ecological soil properties, such as nutrient supply and retention, and water movement. For example, mafic mantle-derived rocks typically weather to a smectite and Fe (hydr)oxide-rich colloidal fraction with the simultaneous release of Ca and Mg for use by plants and soil organisms. The smectites provide high cation exchange capacity (CEC), which can easily retain nutrient cations. Felsic crust-derived rocks tend to weather to a kaolin- and gibbsite-rich colloidal fraction with release of Ca and K for use by the biota. Kaolin and gibbsite provide only a small amount of cation exchange capability, leading to relatively rapid leaching of nutrient cations. The presence of quartz in the felsic rocks provides a skeletal framework of resistant sand size grains that tends to promote water percolation. In contrast, the smectites derived from mafic rocks tend to form clay-rich horizons. The clays tend to swell when wet, which can reduce water flow by closing off macropores. Often igneous rocks contain a broad suite of minerals that weather to provide a mixture of nutrients and a diverse array of secondary minerals. In contrast, limestone is quite pure calcite, which should only release Ca and H_2CO_3 when it reacts with water. Soils forming on limestone often have inherited their colloidal fraction from weathering of impurities in the rock or from eolian addition. Similarly, soils forming on quartz sandstone or quartzite must inherit their colloidal fraction from eolian input.

30.2.2 Energy: Water, Temperature, and Biology

Soil development is strongly dependent on energy that is ultimately provided by the sun and Earth's gravitational field. Soil is heated directly by energy absorption at the surface and indirectly by transfer from the atmosphere. These processes set up superimposed diurnal, seasonal, and annual waves of energy moving through soil profiles. Soil is cooled by latent heat transfers or through long-wavelength emissions. Soil provides short-term storage of water in the global hydrological cycle, which moves water from oceans to the atmosphere and back. Rain and snowmelt provide water to soils through downward infiltration under the influence of gravity and adhesive forces. Within soil profiles, water is held by adhesive and cohesive forces; however, once the water-holding capacity is exceeded, water can move downward to the groundwater table or laterally to river systems. Evaporation and transpiration remove water directly from the soil surface and from plant leaves. Plant roots collect water from much greater depths, thus extending greatly the role of latent heat flux in driving land–atmosphere hydrologic transfers.

During Earth's history, evolution of photosynthesis and establishment of rooted plants on land initiated a powerful source of energy to drive pedogenesis. Photosynthesis produces complex organic molecules, which are shed to the soil either directly or after they have cycled through animals. In the soil, organic matter is metabolized by microorganisms; this process (often called soil respiration) releases the CO_2 and water that was utilized in photosynthesis. The paired photosynthesis and soil respiration reactions set up a giant planetary reduction–oxidation cycle involving carbon and oxygen. Carbon in CO_2 is reduced to organic compounds; O in water is oxidized to molecular form. In turn, microbial breakdown of organic compounds oxidizes C back to CO_2, transferring electrons to O_2, which is reduced to

water. Photosynthesis captures massive amounts of solar energy and much of the ensuing organic matter is transferred to the soil, where its breakdown by soil's vast microbial populations provides most of the energy that drives pedogenesis. Without water, nutrients, and an appropriate temperature range, biological reactions cannot function, but once these environmental conditions are met, it is the C–O redox cycle that releases organic acid into soil, which, in turn, drives specific pedological transformations.

Organic acids lower the pH of soil solution thereby enhancing mineral weathering, but the release of cations during weathering acts to neutralize the acidity. The amount of water percolation and cation removal determines the extent to which weathering buffers soil pH against acidification and determines the nature of secondary mineral synthesis. In well-drained humid environments, dilute soil solution leads to strong chemical gradients, intense weathering, efficient leaching of soluble components (basic cations and silicic acid), and secondary mineral synthesis involving only the least soluble components (Fe and Al (hydr) oxides and kaolin minerals). In poorly drained sites, soil solution accumulates highly soluble ions, as well as sparingly soluble ions, leading to synthesis of smectite (in environments with high Si and Mg activity) and other minerals. In these soils, Fe and Mn may be reduced and slowly leached away. In contrast, arid environments often have soil solutions that contain large concentrations of ions, leading to minor chemical gradients, short leaching distances for only the most soluble ions, and secondary mineral synthesis that is dominated by ionic salts (calcite, gypsum, halite, etc.). Thus, long-term average soil solution concentrations determine most pedochemical properties. Furthermore, they help to condition the terrestrial portion of many biogeochemical cycles because elements released by weathering and not utilized biologically or assimilated into pedogenic minerals are rapidly leached from soil into groundwater, rivers, lakes, and oceans (Berner and Berner, 1996).

The annual amount and seasonal distribution of precipitation and solar energy define broad life zones or biomes based on ecosystem composition and productivity (Aber and Melillo, 1991). Up to some maximum, increasing rainfall leads to greater net primary production of C, which, in turn, leads to greater production of organic matter and more rapid rates of nutrient cycling (Schlesinger, 1997). Highly productive ecosystems often have high levels of CO_2 and enhanced organic acid production, which lead to low soil solution pH values and high weathering rates that release more nutrients until their store of primary minerals is exhausted. Temperature controls the rate of biological processes and mineral weathering/synthesis. At 0°C, and below, little water is available to mediate chemical reactions. In extremely cold environments, physical disintegration of rock material often predominates over chemical breakdown of minerals. For each 10°C increase, biologically mediated reaction rates double until the upper limit of enzymatic functioning is reached. This implies that, all other things being equal, soils in tropical environments will receive far more yearly heat energy and will be more chemically weathered than those in arctic environments (Ugolini and Spaltenstein, 1992; van Wambeke, 1992). In hilly and mountainous terrain, precipitation and solar energy inputs are modified by local topographic position. Soil moisture varies along hillslopes because of redistribution from convex to concave positions, with consequent impact on vegetation type and productivity. Locally, sites are drier or moister than are predicted by average climatic parameters. Similarly, local relief modifies the angle and duration of solar illumination and hence temperature.

In addition to capturing solar energy by photosynthesis, plants have more direct influences on soil formation. The locus of deposition of dead plant material is a factor determining the nature of near-surface horizons. In forests, periodic litter fall deposits organic matter on the soil surface resulting in O horizons. Litter partly decomposes in the O horizon, releasing residues that are carried to the mineral soil in solution as colloidal flow or mixed into the mineral soil by soil fauna. Downward movement of organic acids provides chelating power, which can produce horizons of depletion in the mineral surface soil (E horizon), where one might expect to find organic accumulation (A horizon). In contrast, grasslands tend to be dominated by fire, which releases nutrients as ash at the soil surface, and they shed more organic matter as dead roots and root exudates in the mineral surface soil horizons (producing A horizons). When trees fall, soil and underlying geologic material are often pulled up with the root mass, acting to mix and destroy existing horizons. Roots break up geological substrate through physical expansion and enhance chemical weathering by exuding acidic molecules. In this way, they produce preferential flow paths where pedogenic processes are intensified. Roots fuel nutrient cycling by providing a direct conduit for nutrient movement from soil to aboveground plant parts, which are eventually returned to the upper soil horizons. Mycorrhizal fungi associated with the roots of many plant species are particularly good at decomposing mineral substrate to release P (Chapter 27).

Roots are an important source of food for animals that burrow for food or shelter. Fossorial mammals are effective at mixing parent material fabric and soil horizons. They can sort particle sizes and create macropores that direct preferential water flow. Smaller animals are equally effective at driving processes that enhance or retard specific vectors of soil formation. Ants, termites, springtails, and earthworms move organic matter from the surface downward, mix soil horizons, and create macropores. On hillslopes, animals that deposit soil material on the surface can significantly enhance downslope redistribution of mass through their diggings.

30.3 Pedogenic Processes

In combination, environmental variables drive processes that act on geological or preexisting soil substrate to effect pedogenic alteration at scales ranging from the microscopic parts of soil fabric to watershed soil mantles. Commonly, there will be many processes acting partly in conjunction and partly in opposition. In their totality, they produce soil bodies with recognizable horizons.

In some cases, continued enhancement of horizon properties can, itself, modify ongoing processes, changing the vector of soil formation, and initiating horizon deterioration.

Understanding soil formation requires measurement of present processes, prediction of future trends based on these processes, and interpretation of past processes based on present, relict morphology. A large body of pedological research informs this chapter. The authors have not referenced most of it, choosing instead to focus on essential concepts and specific examples.

30.3.1 Conceptual Process Model

A given body of in situ soil material, regardless of size, can be altered by additions, losses, transformations, or translocations (Simonson, 1959). These processes interact differently depending on the depth from the soil surface and the mix of environmental variables at a specific location. Some of these processes lend themselves to mass balance calculations, others to use of specific tracers or extractions, but, in general, there is no single, universal approach that will provide knowledge of these four processes.

30.3.1.1 Additions

Soil is formed when C (and N) is added from the atmosphere by biological fixation processes. Enzymes in plants and associated microorganisms reduce atmospheric components into biologically useful forms. Dead plants and animals feed a host of microorganisms, which utilize their C and N for growth and energy. Residues from these processes accumulate in soils in complex forms collectively known as soil organic matter (SOM). Since addition of organic residues is greatest near the surface, soil functioning can sometimes be conceptualized into two compartments: an upper part where organic acids and microbial dynamics hold sway and a lower part where inorganic processes dominate, though still influenced by organic processes. It is the mixture of SOM with the porous matrix of inherited and newly synthesized minerals that fundamentally defines Earth's soils.

Solutes and particulate matter are added to soils either directly from the atmosphere (Simonson, 1995; Derry and Chadwick, 2007) or by movement from topographically higher points in the soil landscape (Paton et al., 1995). Although these added components are often incorporated with little outward evidence of their influence, their role can be significant, such as when ecosystems growing on highly weathered soils are sustained by nutrients added from atmospheric sources. Atmospheric additions provide nutrients to rainforests that have inherently low fertility, sometimes providing the majority of nutrient inputs to the ecosystem (Chadwick et al., 1999; Okin et al., 2004; Pett-Ridge, 2009). When additions are rapid and large, existing soils may be buried and new soils developed on the added material. An intermediate result is formation of cumulic soils where soil formation continues as new matter is added at the surface, thickening the soil, as may occur along the lower portions of hillslopes where matter eroded form higher positions accumulates or in areas receiving moderate amounts of airborne dust (Chapter 29).

30.3.1.2 Losses

Mass is lost from soils through erosion by wind and water at the surface and by leaching of solutes and colloids. Eroded soils often lie on the upper slope portions of hillslopes. Microbes break down SOM and minerals weather, releasing ions to the soil solution. In the organically dominated soil compartment, organic chelates facilitate movement of ions deeper into the profile. When excess water moves through soil pores, some elements are carried into streams or groundwater. Typical cations lost through leaching are Na^+, Ca^{2+}, K^+, Mg^{2+}, and as soil acidity increases, smaller amounts of Al are leached in the form of variously charged hydrolysis products. Except at pH values >9, $Si(OH)_4$ is leached as an uncharged compound. Anions leached from soil are dominated by HCO_3^-, which leads to significant amounts of atmospheric carbon sequestration on geological timescales (Chadwick et al., 1994). Lesser amounts of NO_3^- and SO_4^{2-} are leached from soils, but those receiving acid rain may show large losses of these anions (Sposito, 1989). Under aerobic conditions, little Fe is leached from soils and both Fe and Al tend to accumulate by residual enrichment because of leaching of other elements. Iron and Mn can be leached from soils under anaerobic conditions because their reduced forms are soluble.

30.3.1.3 Transformations

Organic matter added to soil is modified by microbial respiration leading to accumulation of more complex SOM or organic compounds that bond with inorganic colloids. Weathering of parent material minerals provides not only nutrients for biological activity but also building blocks for synthesis of secondary minerals. Compared with mantle- and crust-derived minerals that form soil parent material, secondary minerals are enriched in stable elements such as Al and Fe and depleted in easily solubilized elements such as base cations and Si. Under humid, well-drained conditions, where leaching is maximized, secondary mineral formation is characterized by synthesis of aluminosilicate clays and Al and Fe (hydr)oxides. In arid environments, leaching is negligible and even basic cations accumulate in the lower parts of soil profiles as soluble and semisoluble salts. These chemical transformations also lead to physical transformations. For example, wetting and drying results in swelling and shrinking that transform soil fabric, producing a structure reflective of its mineralogical, textural, and organic matter status. Smectite, vermiculite, and short-range order clays hold much more hydroscopic water than do the primary minerals from which they form. Chemical and mineralogical transformations can not only release nutrients for biological use but also sequester nutrients. Nitrogen can be immobilized by NH_4^+ fixation in clay minerals and P can be fixed by sorption onto Fe and Al (hydr)oxides at low to neutral pH values and precipitation with or adsorption to $CaCO_3$ at high pH values.

30.3.1.4 Translocations

Colloids, composed of low-molecular-weight organic matter and small clay particles, and dissolved constituents can move through soil pores. Commonly, the location of mobilization and deposition are controlled by complex chemical interactions between soil solution and the colloidal fraction. Translocation in humid environments usually is effected by downward flow of water. In arid environments, it is often downward as well, but salts can also be carried upward by capillary flow of water in response to evaporation. These processes lead to formation of zones of colloid and solute depletion, such as E horizons, and zones of colloid enrichment and solute precipitation, such as Bhs (≈spodic), Bt (≈argillic), Bk (≈calcic), By (≈gypsic), and Bqm (≈duripan) horizons. Another class of translocations includes mixing processes, which move bulk soil material upward, downward, or laterally in the soil. Mixing can be caused by activity of soil organisms, freeze–thaw cycles, or shrinking and swelling of expansive clays. These processes counterbalance colloid redistribution because they stir soil profiles, preventing or slowing concentration of translocated materials in subsurface horizons.

30.3.2 Dominant Processes

Locally, soil processes reflect a balance among gains, losses, internal redistribution, and chemical and physical changes. The resulting soil properties represent the long-term effect of these processes acting on a 3D reaction column that is open to exchange of matter and energy with the environment. Important soil-forming processes are described later, beginning with two universal aspects of soil formation: organic matter accumulation and formation of soil structure. Subsequent sections are organized to cover processes that are driven by water flux and to some degree, reflect the influence of progressively greater leaching: accumulation of soluble salts and gypsum, accumulation of $CaCO_3$, accumulation of opaline silica, redistribution of clay, complexation and redistribution of Fe and Al, leaching of Si, and concentration of resistant (hydr)oxides. Next, the processes in soil environments where the presence of water is so prevalent that it greatly limits the supply of O are discussed. In these soils, microbially induced reduction controls important aspects of the chemistry, mineral transformation, and morphology. Finally, biological and physical processes of soil mixing are considered. Soil mixing occurs to some degree in most soil-forming environments but is especially influential under some conditions, such as in the seasonally thawed layer above a permafrost table.

30.3.2.1 Organic Matter Accumulation and Alteration

The primary source of organic matter in soils is vegetation, with leaves, stems, and floral parts added to the surface as they drop from the plant, and roots added directly into the soil itself as they grow. Animals and microorganisms (Part IV) feed on the vegetable matter, and each other, decomposing the organic matter parent material to yield gases (e.g., CO_2, CH_4) and humus. The influence of SOM is out of proportion to its weight fraction,

a reality that is recognized in the designation of soil materials as organic when they contain a minimum of only 12%–20% organic C. The organic fraction of soils can be extremely important in determining many aspects of soil processes. For example, even in soils with as little as 0.5%–1% organic C, SOM controls pesticide adsorption.

30.3.2.1.1 Organic Matter Decomposition

Soil organisms use organic tissues as a source of energy and C. Each type of organism has its own role in the decomposition process, from primary decomposers, such as beetles, ants, termites, earthworms, and fungi, to decomposers that feed on the feces or tissue of the primary decomposers, such as bacteria, fungi, and various meso- and macrofauna. A succession of populations operates, each using the altered material from the previously active population and further altering the organic substrate itself. The result is a successive depletion of chemical energy sources, increased resistance to microbial attack, and a lowering of the C:N ratio of the SOM.

The rate of decomposition is controlled by a number of factors related to organic matter quality, the interaction of organic matter with soil minerals, and environmental conditions that affect biological activity. The amount and kind of the various compounds in the organic matter are critical (Melillo et al., 1989). Simple organic acids, sugars, and starches are very quickly utilized by microorganisms (on the order of days to months). Protein, chitin, cellulose, and hemicellulose are used less rapidly and are listed in order of increasing resistance to decomposition. Lignin, fats, and waxes are most resistant to decomposition.

Association with soil minerals can be an important factor in stabilizing organic matter against decomposition. In a study of organic matter in subsoil horizons of acidic forest soils, 73% of stable organic matter was found to be mineral protected (Mikutta et al., 2006). Furthermore, most variability in the size of the mineral-protected organic matter pool was explained by the concentration of poorly crystalline minerals. Soils dominated by short-range order minerals have slowly decomposing organic carbon pools that are larger than those of other mineral soils (Rasmussen et al., 2006). The high surface area of these minerals adsorbs organic carbon, decreasing its availability for decomposition, resulting in relatively slow decomposition rates.

Biological activity in soils is greatest when the soil pH is between 6 and 8, soil temperature is 20°C–40°C, soil water potential is between field capacity and about −1.5 MPa, and there are no deficiencies in essential nutrients. Rates of decomposition are especially slow when the soil is saturated for long enough to become anaerobic and when the temperature is below biological zero (≈5°C). Under these conditions, thick layers of organic matter (>40 cm) may accumulate above the mineral soil. On the other hand, there are microbes adapted for virtually every condition that may come about naturally in soils (Atlas and Bartha, 1981).

30.3.2.1.2 Characteristics of Soil Organic Matter

Soils may contain organic matter ranging across the entire spectrum of decomposition products, particularly if a mixing

mechanism, such as burrowing animals or surface cracks, operates to incorporate fresh organic material into the soil (Quideau et al., 1998). In the absence of aggressive mixing, much decomposition occurs within a litter layer. In general, SOM is increasingly decomposed with depth. The final product is humus: the dark brown, complex, microbially resistant, colloidal compounds that are highly modified original materials or materials synthesized by microbes. Humus has high surface area and chemical reactivity (CEC ranges from 100 to 300 $cmol_c$ kg^{-1}), is very hydroscopic, and readily forms complexes with the inorganic fraction (Chapter 11). Humus is so complex that its composition is usually defined using the following operational criteria (Oades, 1989): fulvic acid fraction, which is soluble in both alkali and acid, humic acid fraction, which is soluble in alkali but insoluble in acid, and the humin fraction, which is insoluble in both alkali and acid. Fulvic acid is composed of the lowest molecular weight compounds and has the greatest number of acid groups and the highest CEC. In contrast, humin is composed of the highest molecular weight compounds and has relatively few acid groups and the lowest CEC. In soils of pyrogenic ecosystems, charcoal may be a significant component of the carbon pool (MacKenzie et al., 2008). Carbon in the form of charcoal is highly resistant to decomposition and influences nutrient availability.

30.3.2.1.3 Relationship of Organic Matter to Morphology and Function

The accumulation of humified organic matter is key to formation of an A horizon, which, if it becomes thick enough, may evolve to qualify as a mollic or umbric epipedon. A horizons are an important link between soils and plants, since most plant roots exist within the A horizon and most of the nutrients are extracted from there. Decomposition of organic matter in the A horizon, including the roots themselves, biocycles essential nutrients from vegetation back into plant-available pools. High levels of organic acids lead to maximum rates of primary mineral decomposition in A horizons as well. Addition of organic matter also influences the physical properties of soils. As the A horizon develops in young soils, there is a decrease in bulk density, and the soil color becomes darker and redder (Turk et al., 2008). Organic matter tends to promote development of soil structure and porosity, thereby enhancing water infiltration and water-holding capacity.

30.3.2.2 Development of Soil Structure

An essential component of soil development is the substitution of soil structure for the geologic structure of parent material. While geologic structure is inherited from jointing cracks and bedding planes, soil structure forms as a function of shrinking and swelling induced by change in moisture content and by the downward movement of water and colloids along preferential flow lines. Soil structural units, known as peds, become more strongly expressed as their faces are differentiated from their interiors. The surface/interior differentiation comes about through several mechanisms. Wetting-induced expansion forms pressure faces or stress argillans by orienting platy silt and clay particles along

contact planes between peds. Subsequent drying causes contraction, which opens voids between peds. Upon rewetting, water flows preferentially through the contraction voids depositing clays and organic matter on the ped faces, further differentiating the outer from the inner parts of the peds. Other compounds, including calcite, silica, and Fe and Mn (hydr)oxides can also be deposited along ped faces. Conversely, under some conditions, outer margins of peds become depleted by preferential leaching of clay and soluble compounds. Roots follow paths of least resistance and concentrate in voids between structural units, enriching ped surfaces with organic matter and enhancing preferential drying of ped exteriors relative to interiors.

30.3.2.2.1 Size, Degree of Expression, and Reinforcement of Peds

A number of factors influence the size and degree of expression of soil structural units. The amount of volume change associated with wetting and drying cycles (swelling and shrinking) is very important. Fine-textured soils and those with smectitic mineralogy typically have relatively large volume changes and, therefore, develop the most strongly expressed structural units. Fine-textured soils also have less resistance to shear and so tend to have more cracks and finer structural units. Frequent shrink/swell cycles, which can be related to cyclic drying/wetting, tend to reinforce the expression of structural units (Southard and Buol, 1988). This is reflected in the development of soil structure in shallow agricultural drainage ditches that undergo cyclic drying/wetting but not in deeper ditches that are continually saturated (Vaughan et al., 2008). Slow drying allows a relatively uniform shrinkage and contraction of the soil mass, producing larger peds. Crystallization of salts in saline soils yields a finer structure than is found in similar nonsaline soils (Reid et al., 1993).

30.3.2.2.2 Granular Structure in Surface Horizons

The structure of surface horizons is often most strongly influenced by biological factors, including organic matter, microbes, plant roots, and soil fauna (Figure 30.1). Fecal casts of soil macrofauna, such as earthworms (Lee and Foster, 1991) and snails (Anderson et al., 1975), often form compact, stable aggregates, which dominate in some A horizons. Dense networks of fine grass roots and fungal hyphae cause uniform fine-scale shrinkage cracks and enmesh soil materials into granular or crumblike units (Oades, 1993). At the most fundamental level, soil aggregates in surface horizons are usually held together by SOM–mineral complexes (Chapters 3 and 11).

30.3.2.2.3 Platy Structure

Platy structure typically forms in response to unidirectional compressional forces (Figure 30.1). It is most often produced in surface soils through compaction by animals or machines, or by raindrop impact. Vertical compaction yields horizontally oriented, platy structural units. Gravity can contribute to the necessary vertical force for platy structure development in the silty vesicular horizons that are common in arid and semiarid regions. In these surface horizons, vesicles are formed by escaping gases as the soil material is wetted. Repeated wetting and

Type of structure	Soil environment	Formation processes
Granular	A horizon	Aggregation by biological agents: organic compounds, fungal hyphae, fine roots, fecal casts
Platy	A and other surface horizons Petrocalcic horizons Duripans	Vertical compression from compaction
Prismatic	B horizons with uniform texture, fine roots, few coarse fragments, relatively slow drying	Horizontal compression from shrink-swell
Blocky	B horizons with coarse fragments, heterogeneous root sizes	Shrink-swell interrupted by nonhomogeneous matrix

FIGURE 30.1 Types of soil structure, their occurrence within soils, and the processes responsible for their formation.

drying cycles enlarge the vesicles until they can no longer support the weight of the overlying material and collapse, forming planes that bound platy structural units (Miller, 1971). Platy structure is also common in highly developed petrocalcic horizons and duripans. The origin of platy structure in these subsoil horizons is less clear but may be caused by vertical compression generated as precipitation of secondary calcite and opal increases subsoil volume. In pergelic soils (Gelisols), platy structure is associated with the formation of lenticular ice (vein ice) (Section 33.6)

30.3.2.2.4 Prismatic and Blocky Structure

Shrinkage of moist soil material as it dries results in multidirectional compression centered around numerous loci within the mass. When shrinkage forces are largely resolved in lateral directions, the soil material may contract uniformly toward more or less equally spaced centers forming prismatic or columnar peds bounded by vertical cracks (Figure 30.1). In the formation of prismatic structure, uniform shrinkage is important because it develops the consistently spaced and arranged cracks that form ped boundaries; uniform shrinkage is favored by slow drying and homogeneous soil materials. It is often associated with uniformly fine-textured sediments in poorly drained, low-lying landscape positions. Prismatic or columnar structure is common in natric horizons because of enhanced swelling and poor drainage associated with Na-saturated clays. In contrast to the elongated character of prismatic structure, blocky structure forms as a result of combined lateral and vertical shrinkage forces (Figure 30.1), with neither predominating. Conditions favoring blocky structure development are rapid drying and factors that break continuity of soil fabric, such as woody roots and coarse fragments. Also, bedded moderately fine and fine-textured fluvial or marine deposits tend to form blocky structure in B horizons because horizontal planes of weakness, inherited from parent materials, are bisected by vertical shrinkage cracks. In permafrost soils, blocky structure is associated with ice nets, a cryostructure consisting of 2–5 cm diameter polygons separated by vertical or diagonal desiccation cracks (Ping et al., 2008).

30.3.2.2.5 Vertic Features

Vertisols and other clayey, expansive soils develop characteristic structural features as a result of their dynamic shrink/swell behavior (Section 33.7). Upon wetting, the fabric of these soils swells, commonly increasing its volume by about 10%–15%. In surface horizons, this increase in volume is accommodated by upward movement, but in the subsoil, overburden pressures confine vertical movement so that lateral swelling pressures are at least four times as great as the vertical pressures and exceed the soil shear strength (Wilding and Tessier, 1996). Under these conditions, shear failure takes place at angles between 10° and 60° from horizontal. The shear planes present slick, grooved surfaces, known as slickensides that bound characteristic wedge-shaped aggregates.

30.3.2.2.6 Aggregation by Fe and Al (Hydr)oxides

Highly weathered soils, such as Oxisols, have a fine (<2 mm diameter) granular structure that is the result of aggregation by Fe and Al (hydr)oxides (van Wambeke et al., 1983) (Section 33.13). Aggregation is affected by very small positively charged Fe and Al (hydr)oxide particles and surface coatings that form bridges between negatively charged clay particles to build up small aggregates (Hsu, 1989; Schwertmann and Taylor, 1989).

30.3.2.3 Accumulation and Redistribution of Salts

Gypsum and more soluble salts accumulate in poorly leached soils and soils where evapotranspiration (ET) greatly exceeds leaching. The composition and concentration of soluble salts

influence the physical behavior of soil particles because of the effect that dissolved salts have on dispersion and flocculation. Ecosystems with salt-affected soils are subject to many plant physiological stresses, related to surface crusting, low osmotic potential of the soil solution, and specific ion toxicities.

30.3.2.3.1 Characteristics of Soluble Salts

Sulfate, carbonate, chloride, and nitrate salts occur in soils of arid environments (Table 30.1). The concentration and type of salts influence the physical behavior and chemical properties of the soils in which they occur. Salt-affected soils have major impacts on the flocculation or dispersion of clay minerals and organic matter (Chapters 17 and 18 of *Handbook of Soil Sciences: Resource Management and Environmental Impacts*). In general, high electrolyte concentrations keep soils flocculated, whereas colloidal dispersion occurs when the electrolyte concentration is low and Na predominates on exchange sites. Thus, sodic soils [exchangeable sodium percentage (ESP) > 15, electrical conductivity (EC) < 4 dS m^{-1}] are dispersed, resulting in clogged pores and very low infiltration rates, whereas saline (ESP < 15, EC > 4 dS m^{-1}) and saline-sodic (ESP > 15, EC > 4 dS m^{-1}) soils are flocculated, promoting porosity and higher infiltration rates.

Salts that occur in arid-land soils vary in their solubilities (Table 30.1). Salts of Na, Mg, and K are more than 100 times more soluble in water than calcite and gypsum and move readily with saturated and unsaturated water flow in soil. As a result of the high solubility of Na salts and the production of hydroxide ions when carbonate ions dissolve, soils containing Na_2CO_3 have high pH values (9–12):

$$Na_2CO_3 + H_2O \rightleftharpoons 2Na^+ + HCO_3^- + OH^- \qquad (30.1)$$
Sodium carbonate can form in sodic soils through several mechanisms. Weathering of Na aluminosilicates releases Na, which reacts with HCO_3^- in water to form $NaHCO_3$, which concentrates

TABLE 30.1 Some Common Salts in Soils and Their Solubilities in Water at 25°C

Name	Formula	Solubility (mol L^{-1})
Soda niter	$NaNO_3$	10.69
Niter	KNO_3	3.53
Halite	$NaCl$	6.15
Thenardite	Na_2SO_4	1.97
Mirabilite	$Na_2SO_4 \cdot 10H_2O$	2.74
Nahocolite	$NaHCO_3$	1.22
Soda	$Na_2CO_3 \cdot 10H_2O$	2.77
Trona	$Na_3H(CO_3)_2 \cdot 2H_2O$	2.56
Bloedite	$Na_2Mg(SO_4)_2 \cdot 4H_2O$	2.31
Hexihydrite	$MgSO_4 \cdot 6H_2O$	3.17
Epsomite	$MgSO_4 \cdot 7H_2O$	3.03
Gypsum	$CaSO_4 \cdot 2H_2O$	0.005
Calcite	$CaCO_3$	0.0006 (pH 8 and $CO_2 = 10^{-4}$ MPa)

to Na_2CO_3 under the influence of evaporation. Neutral Na salts can react with $CaCO_3$ to yield Na_2CO_3:

$$Na_2SO_4 + CaCO_3 \rightleftharpoons Na_2CO_3 + CaSO_4 \qquad (30.2)$$

and Na can be replaced from the exchange by H or Ca from carbonates:

$$[CLAY] - 2Na + CaCO_3 \rightleftharpoons [CLAY] - Ca + Na_2CO_3 \qquad (30.3)$$

30.3.2.3.2 Natural Sources of Soil Salinity

The ultimate source of salts is weathering of primary minerals (Figure 30.2), which produces dilute soil solution. Atmospheric deposition contributes appreciable quantities of salts to soils, particularly as dry fall (dust) in arid regions and as sea spray along coastal margins. Most saline soils receive salts from sources where salts have been concentrated by geological processes. For instance, dissolution of marine or closed basin lake sediments provides preconcentrated salts to near-surface waters. Isotopic studies in the Atacama Desert documented the transition from coastal soils receiving salts from marine sources to inland soils, in which salts have isotopic signatures similar to local surface and ground waters (Rech et al., 2003). The salts in groundwater are concentrated by evaporation within the capillary fringe and precipitate as evaporite minerals on playa surfaces. These evaporite minerals are highly susceptible to wind erosion (Reynolds et al., 2007), which is responsible for the dispersal of salts across the desert landscape. In a study of a Mojave Desert bolson landscape, salts were found to be concentrated in soils on slopes downwind from the playa (Hirmas and Graham, 2011).

30.3.2.3.3 Accumulation of Soluble Salts in Soils

Salts precipitate when their solubility is exceeded, usually as the soil solution is concentrated by ET. In well-drained soils where leaching is greater than ET, salts do not accumulate because the constituent ions are leached to groundwater. On the other hand, salts accumulate when leaching is minimal. Mineral leaching results from high ET rates and/or low rainfall, convex topography that disperses water flow, and soil conditions such as crusting that yield low infiltration rates. One special case of poor leaching conditions leading to salt accumulation involves the soils formed beneath desert pavement (a monolayer of closely packed clasts). The accumulation of salts beneath desert pavement corresponds strongly with the size, sorting, and percent cover of the surface clasts (Wood et al., 2005) and includes large nitrate pools in some soils in the Mojave Desert (Graham et al., 2008). In each of these cases, the areal and vertical distribution of salts reflects a balance between a downward or lateral flux of leaching water that removes salts, and the upward flux of ET that helps retain salts within the soil.

Although the dominant influence of plants on salt distribution is through their role in ET, some plants have a localized effect on soil salinity and sodicity. For example, surface soils under the canopy of grease-wood have EC values six times those of soils in interspaces between the shrubs, and ESP values are

FIGURE 30.2 Sources and redistribution of soluble salts in soils in relation to hydrology, lithology, and landscape position. When the downward leaching flux of water greatly exceeds upward flux due to ET, soluble salts, as indicated by EC of saturation extracts, are minimal throughout the soil profile. When leaching is slightly greater than ET, EC increases with depth, since salts are leached from the surface soil. When ET is greater than leaching, EC is greatest near the surface due to the predominating upward flux of water, carrying salts, to the evaporative surface.

more than 10 times greater due to biocycling of sodium ions (Fireman and Hayward, 1952).

Bare patches, known as slickspots, caused by salt accumulations, have been shown to grow due to interactions between the vegetation and soil properties (Reid et al., 1993). The grass-covered soils surrounding the slickspots have adequate infiltration rates and grass traps saline dust from a nearby soda lake

FIGURE 30.3 Diagrammatic representation of processes contributing to the salinization and expansion of slickspots on the Carrizo Plain, California. (Modified from Reid, D.A., R.C. Graham, R.J. Southard, and C. Amrhein. 1993. Slickspot soil genesis in the Carrizo Plain, California. Soil Sci. Soc. Am. J. 57:162–168. With permission of the Soil Science Society of America.)

playa (Figure 30.3). Under the slickspots, the much lower infiltration rates at the surface causes the subsoils to remain dry even during the wet season. This, in turn, establishes a matric potential gradient from the moist subsoils under grass to the slickspots, so that salts are carried laterally in solution as water is drawn by capillarity into the slickspot soils. The buildup of salts in the slickspot soils eventually has a toxic effect on the grasses at the slickspot margin, which exposes bare soil to raindrop impact and wind erosion, thereby promoting expansion of the slickspot.

30.3.2.3.4 Relation to Soil Morphology

Accumulation of soluble salts may be expressed in a morphological sequence similar to the stages of carbonate accumulation (discussed in the Section 30.3.2.4). Soils in stable landscape positions and hyperarid deserts, such as the Atacama Desert in South America and the Dry Valleys of Antarctica, can eventually develop horizons that are indurated with highly soluble minerals, including halite and soda niter (Bockheim, 1997; Rech et al., 2003). Soluble salt accumulation in moraines of the Transantarctic mountains progress with age from coatings on the bottoms of stones (stage I), to flecks (stages II–III), to a cemented pan (stages IV–V), and finally an indurated pan (stage VI) (Bockheim, 1990). In some cases, the morphology of salt accumulations may be a clue to their composition. Concentrations of gypsum may be identified in the field by a unique morphology, called gypsum snowballs, which are 0.5–1 mm, white, powdery spheres (Buck and Van Hoesen, 2002).

Exchangeable sodium can influence soil morphology by causing clay dispersion, which decreases aggregate stability and increases mobility of clays. Illuvial clay accumulates more rapidly in sodic soils, compared to nonsodic soils, thus complicating the relationships between soil morphology and surface age (Peterson, 1980). Strong development of vesicular horizons has been associated with sodic soils, due to dispersion and crust formation (Bouza et al., 1993).

The contrast between leached soils and salt-affected soils is well illustrated by the comparison of soils in slickspots with the surrounding vegetated landscape (Reid et al., 1993). The grass-covered soils have clayey Bt horizons with strong prismatic structure, which allows rapid infiltration of rainwater and leaching of salts. In these soils, less-soluble minerals occur near the surface and more-soluble minerals are concentrated deeper in the profile. With increasing depths, accumulations of calcite, gypsum, and soluble salts are observed, indicating a regime in which leaching predominates over ET. In contrast, <1 m away, the bare surface of the slickspot is crusted from raindrop impact, and the upper few centimeters are sufficiently leached of salts, so that the soil disperses. Crusting and dispersion result in very low infiltration rates, so that leaching of the profile is minimal. The predominance of evaporation over leaching is indicated by the accumulation of soluble salts above gypsum, and calcite accumulation deeper in the soil a trend opposite that in grassed areas (Figure 30.3).

30.3.2.4 Accumulation and Redistribution of Calcite

Where soil pH values are above about 7.2, $CaCO_3$ can precipitate in soils to form the mineral species calcite. Calcite contains <5 mol% Mg. At 25°C, pH 8, and P_{CO_2} of 10^{-4} MPa, calcite has a solubility of 0.0006 mol L^{-1} (0.06 g L^{-1}), which is much more soluble than silicate minerals but is considerably less soluble than the salts commonly found in soils. Under well-drained conditions, calcite is found in soils of arid, semiarid, and subhumid environments. With progressively greater leaching, it is found at greater depths below the soil surface. It can also accumulate in poorly drained soils where calcium and bicarbonate are concentrated in ponded water.

30.3.2.4.1 Natural Sources of Calcite in Soils

While calcite may be inherited in soils from parent materials such as limestone, pedogenic calcite precipitates from soil solution and requires sources of Ca^{2+} and CO_3^{2-} ions. Calcium ions may be derived from weathering of parent materials. Calcareous rocks provide the most abundant Ca, with limestone containing 30%–40% Ca and dolomite containing about 20% Ca. Calcareous tills, loess, and other sediments also provide a ready supply of Ca for pedogenic calcite formation. Calcium is present many in primary minerals, particularly Ca-rich plagioclase, but also in some amphiboles, pyroxenes, garnets, and epidote. Among igneous rocks, Ca is most abundant in the more mafic (but not ultramafic) rocks, such as gabbro and basalt, which contain about 7% Ca. Mafic rocks are also rich in Mg and soils formed on basalt may contain pedogenic high-Mg calcite and/or dolomite (Capo et al., 2000; Whipkey et al., 2002). Atmospheric deposition can be a substantial, even dominant, source of Ca, both in ionic form and as particulate $CaCO_3$. For example, in southern Nevada and California, dust contains 10%–30% $CaCO_3$, equating to a deposition rate of 1–6.6 g $CaCO_3$ m^{-2} $year^{-1}$ (Reheis and Kihl, 1995). In southern New Mexico, dust contributes about 0.4 g $CaCO_3$ m^{-2} $year^{-1}$, whereas rain delivers 1.2 g m^{-2} $year^{-1}$ (Birkeland, 1999). On the Edwards Plateau in Texas, no $CaCO_3$ is delivered

as dust, but rain supplies Ca equivalent to 2.3 g $CaCO_3$ m^{-2} $year^{-1}$ (Rabenhorst et al., 1984). In southern Arizona, isotopic studies have suggested that most $CaCO_3$ in dust actually comes from the erosion of soil carbonates; thus, dust can be viewed as a recycled source of Ca (Capo and Chadwick, 1999; Naiman et al., 2000). Pedogenic carbonates have a Sr isotope signature between that of dust and parent rock, indicating a mixed source of Ca. Calcium can also be derived from biocycled plant material and groundwater, which may be highly calcareous, depending on the lithologies exposed in the aquifer. When Ca-laden groundwater lies within or just below the soil zone, calcite can form in the soil as it is precipitated within the capillary fringe. At sites near the coast, Sr isotope ratios in pedogenic carbonates are similar to those of ocean water, suggesting that some Ca may come from sea spray (Naiman et al., 2000; Whipkey et al., 2000).

The source of the carbonate anion in calcite is the dissolution of CO_2 in water, which yields the following species:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \qquad (30.4)$$

$$H_2CO_3 \rightleftharpoons HCO_3 + H^+ \quad pK = 6.4 \qquad (30.5)$$

$$HCO_3 \rightleftharpoons CO_3^{2-} + H^+ \quad pK = 10.3 \qquad (30.6)$$
The amount of CO_2 in the soil solution depends on the relationships expressed in Henry's law:

$$K_H = \frac{(H_2CO_3)}{P_{CO_2}} = 10^{-1.5} \qquad (30.7)$$

An increase in the proportion of CO_2 in the gas phase increases the CO_2 concentration in the solution in contact with the gas. The P_{CO_2} in soils is on the order of 0.003–0.03, compared to 0.00033 in the atmosphere. The distribution of CO_2 in soils depends on a balance between production of CO_2 within the soil, by microbes and plant roots, and diffusion losses of CO_2 out of the soil to the atmosphere. As an example, the CO_2 concentration in a coarse-textured soil in southern Nevada was greatest in spring when biologic activity was at its peak (Figure 30.4; Terhune and Harden, 1991). Even at this time, CO_2 concentration in the surface soil was less than that in the subsoil due to diffusional losses to the atmosphere. Biologic activity and CO_2 production were low during the winter due to cold temperatures and during summer due to dryness.

30.3.2.4.2 Calcite Precipitation in Soils

The reaction for calcite precipitation can be expressed as follows:

$$Ca^{2+} + 2HCO_3 \rightleftharpoons CaCO_3 + H_2O + CO_2 \qquad (30.8)$$
Precipitation of calcite is promoted by a number of factors that influence this relationship. An increase in pH drives the reaction to the right by supplying more HCO_3^-, as a result of $CO_2 + OH^-$. Decreasing the P_{CO_2}, through the loss of CO_2 to the atmosphere,

FIGURE 30.5 Idealized diagram of processes involved in calcite precipitation in (a) a well-drained soil (water flux is downward) and (b) a poorly drained soil (water flux is upward).

also drives the reaction to the right. Loss of water through ET increases the ionic concentration of the soil solution to the point where it exceeds the solubility product of calcite and results in precipitation. Precipitation of calcite in soils is not simply an inorganic chemical phenomenon. In fact, the role of microorganisms seems to be ubiquitous and perhaps essential in pedogenic calcite formation. Microbial influence is revealed by calcified biological structures, such as fungal hyphae, and experimental evidence that shows that both bacteria and, especially, fungi produce calcite as a byproduct of their metabolism. In Ca-rich soils, microbes excrete excess Ca, which concentrates on their external surfaces and reacts with HCO_3^- in the soil solution. In the laboratory, calcite precipitates rapidly in inoculated soil columns but not at all in sterile columns that were otherwise identical (Monger et al., 1991). Hyperarid regions of the Atacama Desert and Antarctica, in which no plant life is observed, have been found to contain only trace levels of $CaCO_3$ (Bockheim, 1990; Ewing et al., 2006; Quade et al., 2007). The isotopic signature of $CaCO_3$ in soils without plant life in the Atacama Desert is distinct from that in soils with plant life, suggesting possible low levels of abiotic precipitation.

Precipitation of calcite in soils occurs preferentially in certain types of morphologic sites. These favored sites include the vicinity of roots, where microbes and nucleation sites are abundant and plant water uptake concentrates the soil solution. Another favorable site is in large pores where drying is relatively rapid and the P_{CO_2} is lower than in the matrix due to effective gas exchange with the atmosphere. In gravelly soils, calcite tends to precipitate preferentially on the undersides of gravels, perhaps because water tends to collect and is last to dry in those sites. Once calcite precipitation is initiated at any of the sites described above, it is preferentially precipitated on preexisting calcite crystals.

30.3.2.4.3 Examples of Calcite Distribution and Precipitation in Soils

The processes governing precipitation of calcite in a well-drained soil, where water flux is downward, are illustrated in Figure 30.5a.
Calcium in the soil originates from weathering, rain, and/or dissolution of dust. Organic matter decomposition in the A horizon produces a high P_{CO_2}, although it decreases substantially near the soil surface due to gas exchange with the atmosphere. The high P_{CO_2} yields a relatively large amount of CO_2 dissolved in the soil solution, producing HCO_3^-. The Ca^{2+} and HCO_3^- ions are leached with soil water to a depth at which calcite precipitates. This depth is determined by decreased P_{CO_2} below the zone of major biological activity and, perhaps more importantly, by the soil solution being concentrated as it enters the dry subsoil and is depleted by ET.

In poorly drained soils of arid and semiarid regions, dominant water flux is upward in response to evaporation (Figure 30.5b). The relatively high water content in subsoil limits gas diffusion, so P_{CO_2} is high and decreases near the soil surface as CO_2 diffuses to the atmosphere. Calcium and HCO_3^- originating from groundwater sources or in situ from the soil move upward with the flux of water. Calcite precipitates in an upper soil zone where the P_{CO_2} is relatively low and the soil solution is concentrated by evaporation.

30.3.2.4.4 Relation to Soil Morphology

Soils with pedogenic calcite commonly progress through distinct evolutionary stages (Table 30.2; Gile et al., 1966). The stages and morphologic expressions are different for gravelly soils compared to fine-textured soils. Because gravelly soils have less total pore space than fine-textured soils, segregated calcite accumulates more rapidly, precipitating readily on pebbles bounded by relatively large pores. One of the distinct morphologic expressions of pedogenic $CaCO_3$ in gravelly soils is pendants precipitated on the bottom of clasts. The pendants grow by precipitation of $CaCO_3$ both at the clast–pendant contact and at the base of the pendant (Brock and Buck, 2005).

TABLE 30.2 Stages of Carbonate Morphology in Soils

Stage	Gravelly Parent Material	Nongravelly Parent Material
I	Thin discontinuous clast coatings; some filaments; matrix can be calcareous next to stones; about 4% $CaCO_3$	Few filaments or coatings on sand grains; <10% $CaCO_3$
I+	Many or all clast coatings are thin and continuous	Filaments are common
II	Continuous clast coatings; local cementation of few to several clasts; matrix is loose and calcareous enough to give somewhat whitened appearance	Few to common nodules; matrix between nodule is slightly whitened by carbonate (15%–50% by area), and the latter occurs in veinlets and as filaments; some matrix can be noncalcareous about 10%–15% $CaCO_3$ in whole sample, 15%–75% in nodules
II+	Same as stage II, except carbonate in matrix is more pervasive	Common nodules, 50%–90% of matrix is whitened; about 15% $CaCO_3$ in whole sample
Continuity of fabric high in carbonate		
III	Carbonate forms an essentially continuous medium in 50%–90% of horizon; color mostly white; carbonate-rich layers more common in upper part; about 20%–25% $CaCO_3$	Many nodules, and carbonate coats many grains such that over 90% of horizon is white; carbonate-rich layers are more common in upper part; about 20% $CaCO_3$ in whole sample
III+	Most clasts have thick carbonate coats; matrix particles continuously coated with carbonate or pores plugged by carbonate; cementation more or less continuous; >40% $CaCO_3$	Most grains coated with carbonate; most pores plugged; >40% $CaCO_3$ in whole sample
Partly or entirely cemented		
IV	Upper part of horizon is nearly pure cemented carbonate (75%–90% $CaCO_3$) and has a weak platy structure due to the weakly expressed laminar depositional layers of carbonate; the rest of the horizon is plugged with carbonate (50%–75% $CaCO_3$)	
V	Laminar layer and platy structure are strongly expressed incipient brecciation and pisolith (thin, multiple layers of carbonate surrounding particles) formation	
VI	Brecciation and recementation, as well as pisoliths, are common

In fine-textured soils, calcite precipitates first as filaments in root pores, then as soft masses. Eventually a calcite-cemented (petrocalcic) horizon forms, in which carbonate plugs nearly all the pores and laminar plates of carbonate build up at the interface between the overlying horizons and the plugged ones. Formation of a petrocalcic horizon (stage IV or greater) has major implications for the direction of further development. Plugged horizons form a barrier to most root penetration. They also resist erosion and the overlying horizons may be stripped off, leaving the petrocalcic horizon exposed at the surface. Burrowing animals and erosion commonly bring fragments of petrocalcic horizons to the surface, where the calcite is dissolved and recycled back into the soil (Eghbal and Southard, 1993).

30.3.2.5 Accumulation and Redistribution of Silica

After oxygen, Si is the most abundant element in Earth's crust. It exists in many primary mineral forms and is incorporated into soil-formed minerals as well. When Si is released by weathering, it is leached and can be lost or can be incorporated into aluminosilicate clay minerals, such as kaolinite or smectite. In humid environments, most Si is either leached or consumed during clay mineral synthesis. In subhumid and semiarid environments where there is enough water to support mineral weathering but not enough to completely leach Si, it can also precipitate as nanocrystalline silica that cements soil horizons.

30.3.2.5.1 Characteristics of Silica in Soils

Silica refers to compounds consisting of SiO_2 in crystalline, poorly crystalline, or amorphous forms, and is sometimes hydrated to some degree. Quartz is a common form of silica in many soils. It is highly crystalline SiO_2 that is inherited from parent materials and usually does not form pedogenically. Opal-A, the common pedogenic and biogenic silica, is a hydrated, x-ray amorphous, form of SiO_2. A somewhat more crystalline form of opal, opal-CT, may form in some very old soils, but it is not nearly as common as opal-A.

30.3.2.5.2 Sources of Soluble Silicon

The weathering of silicate minerals releases Si to solution that can be precipitated, under appropriate conditions, as opal-A. Soils rich in easily weathered silicates, such as olivine ([Mg, Fe]$_2$SiO$_4$) and anorthite (CaAl$_2$Si$_2$O$_8$), release abundant Si into solution. The accumulation of soluble silica in soils of southern California was attributed to feldspars weathering in the upper horizons (Kendrick and Graham, 2004). More resistant silicates, such as quartz, release Si very slowly. Amorphous silica is much more soluble than crystalline forms (Figure 30.6). Volcanic glass is a primary form of amorphous silica, which is abundant in many soils or parent materials, sometimes even in those far from current volcanic activity, since volcanic ash can travel great distances downwind from eruptions. Another source of amorphous silica is
FIGURE 30.6 Dissolution of silicon in water from various silica phases as a function of time. (Reprinted from Drees, L.R., L.P. Wilding, N.E. Smeck, and A.L. Senkayi. 1989. Silica in soils: Quartz and disordered silica polymorphs, p. 913–974. *In* J.B. Dixon and S.B. Weed (eds.) Minerals in soil environments. SSSA, Madison, WI. With permission of the Soil Science Society of America.)

biogenic opal, which is actually opal-A produced as part of plant structures, known as phytoliths, or as part of aquatic organisms, such as diatom tests or sponge spicules. Phytoliths are a biocycled form of silica in soils and can be very abundant in A horizons, particularly in grasslands. In soils that are depleted of primary mineral silica, weathering of phytoliths provides a significant portion of the $Si(OH)_4$ in solution (Alexandre et al., 1997; Derry et al., 2005). Diatoms and sponge spicules are most often found in soils derived from lacustrine, deltaic, or floodplain sediments.

30.3.2.5.3 Dissolution of Silica

Release of Si into solution from a solid is controlled by a number of factors. The inherent solubility of the mineral or amorphous compounds varies widely, with opal-A being the most soluble source of silica (Figure 30.6). Solubility also increases dramatically for very small particles ($<0.01\,\mu m$). External conditions play a large role, with Si solubilization increasing when the soil solution has a low ionic strength, high pH (>9), and relatively high temperature (Drees et al., 1989). Organic acids promote dissolution by complexing $Si(OH)_4$ released into solution, resulting in highest silica dissolution potentials in the root zone. Sorption of Si onto Fe/Al (hydr)oxides can make them a sink for soluble Si, thereby keeping solution concentrations of Si low and increasing dissolution. On the other hand, coatings of organic materials or Fe/Al (hydr)oxides can retard dissolution by isolating the reactive surface from the soil solution. Mobilization of silica in soils of the Pacific Northwest was decreased in response to management practices that promote accretion of organic carbon, presumably due to organic matter coatings on reactive surfaces (Gollany et al., 2005). Solubility of silica increases with increased pressure, a situation that may arise in petrocalcic horizons as calcite crystallization increases the subsoil volume and generates grain-to-grain pressure contacts (Monger and Daugherty, 1991).

30.3.2.5.4 Translocation and Precipitation of Silicon

In solution, Si exists mostly as silicic acid $[Si(OH)_4]$. It moves with percolating water and precipitates when conditions are favorable. The soil pH influences the way in which silica precipitates. At pH < 7, $Si(OH)_4$ precipitates as SiO_2 on adsorption sites as individual molecules or low-molecular-weight polymers, whereas at pH 7–10, Si in solution takes the form of high-molecular-weight polymers, and these are flocculated by cations in solution. Other factors may alter, or override, the effect of pH on Si precipitation in soils. Silica precipitation is promoted in soil solutions with high ionic strength and adsorption is promoted by a solid phase with a high surface area. Release, leaching, and precipitation of Si favors preservation of ^{28}Si in the solid phase of soils, creating strong negative shifts in $\partial^{30}Si$ signatures in soils during weathering (Ziegler et al., 2005a, 2005b).

In soils, $Si(OH)_4$ is adsorbed on exposed hydroxyl groups of clays, (hydr)oxides, and primary silicates (Figure 30.7). A high surface area (e.g., argillic horizon) or ionic strength (e.g., calcic horizon) promotes rapid adsorption of silica as individual or low-molecular-weight polymers. Adsorption is greatest at pH 7–9. Drying dehydrates the adsorbed $Si(OH)_4$ causing amorphous SiO_2 to precipitate on the surface (Figure 30.7a). The strong Si–O bond inhibits rehydration and desorption. The precipitated silica acts as a template for further precipitation (Figure 30.7b) and, eventually, opaline silica forms bridges between the grains on which it precipitates (Figure 30.7c; Chadwick et al., 1987).
FIGURE 30.7 Model of silica precipitation in soils (a) reversible $Si(OH)_4$ adsorption on Fe and Al (hydr)oxides, silicates, and aluminosilicates (M may be Al, Fe, Mg, or Si); (b) further $Si(OH)_4$ adsorption followed by dehydration to SiO_2 during soil drying decreases the reversibility of the original adsorption process; (c) two soil components with $Si(OH)_4$ adsorption surfaces may be bonded together by opaline SiO_2 bridges. (Reprinted from Chadwick, O.A., D.M. Hendricks, and W.D. Nettleton. 1987. Silica in duric soils. 1. A depositional model. Soil Sci. Soc. Am. J. 51:975–982. With permission of the Soil Science Society of America.)

In fine-textured soil horizons, silica diffuses into smaller voids in the soil matrix, where there is more surface area for adsorption, and precipitates as polymerized layers. The zone of accumulation tends to correspond to the zone of clay accumulation because of the abundant sites for precipitation there (Kendrick and Graham, 2004). The silica polymers are found as flocs (≈1 μm diameter) on grains in the soil matrix and interlaminated with clay skins. The same mechanisms apply for coarse-textured soils, but silica not in direct contact with adsorption surfaces may precipitate by flocculation if the ionic strength is sufficiently high (Chadwick et al., 1987). Opaline silica may also precipitate preferentially on the undersides of gravels, even forming pendants (Munk and Southard, 1993).

In many soils of arid and semiarid regions, the depth distributions of silica and calcite overlap, but these pedogenic compounds are concentrated in different microsites by nature of their mode of precipitation. Calcite precipitates by self-nucleation and microbial processes, particularly in larger voids because these dry early, concentrating the soil solution. Larger voids also often have the most effective contact with the atmosphere, so the P_{CO_2} is relatively low. Silica specifically bonds with Al and Fe hydroxy compounds, whereas, under most soil conditions, calcium does not. Thus, silica precipitates primarily by adsorption on surfaces and so is found in the matrix, coating grains, and clay skins, rather than in voids. Furthermore, there is no direct chemical bonding between Ca and $Si(OH)_4$ at pH < 9, since $Si(OH)_4$ is neutral and nonpolar and cannot compete with polar molecules or anions for adsorption on calcite (Chadwick et al., 1987). Coatings of opal also occur as silans in macro voids when the soil matrix is plugged with calcite and silica cements.

30.3.2.5.5 Relation to Soil Morphology

A soil horizon that is thoroughly cemented by silica, such that it will not slake in water or HCl, is known as a duripan. Since the silica needs only to cement the matrix by bridging between grains, cementation can occur with very low concentrations of silica (e.g., ≈4%), particularly in coarse-textured soils. In a chronosequence study of silica accumulation in soils, an increase in rupture resistance was one of the first signs of silica precipitation, observed in 55 ka soils with no macroscopically visible silica precipitation (Kendrick and Graham, 2004). Duripans often have accessory cementing agents, such as Fe (hydr)oxides or calcite. Duripans exhibit two forms corresponding largely to the regional climate. In arid regions, duripans are commonly platy, with plates 1–15 cm thick. Pores and plates are coated with opal and are usually engulfed with pedogenic calcite. In Mediterranean climates, duripans take a different form in which opal coats the faces and pores of very coarse to extremely coarse (0.3–3 m diameter) prisms that make up the subsoil. The upper boundary is abrupt and the pan may have an opal coating on top in the strongly developed cases. Water often perches on top of the pan during the rainy season, so that Fe/Mn (hydr)oxide nodules and illuvial clay accumulate there. The matrix of this kind of duripan is extremely hard when dry but is brittle when moist and can be penetrated, with some difficulty, with a hand auger. Pedogenic calcite may, or may not, be present, but it is not a dominant component.

Reversible, weakly expressed silica cementation seems to play a role in the formation of fragipans. These horizons are dense and appear cemented when dry but will slake in water (Franzmeier et al., 1989; Marsan and Torrent, 1989). The strength of fragipans can be related to the ratio of $Si_d/(Si_d + Al_d)$, suggesting that an accumulation Si under low Al conditions is responsible for the hardening of fragipans, due to the precipitation of amorphous silica rather than aluminosilicates (Duncan and Franzmeier, 1999).

Silica cementation is often enhanced in soils near scarps or incisions, such as at terrace edges. Evaporation at the scarp surface concentrates the soil solution and promotes silica precipitation. The resulting induration impacts water movement and slope retreat, and renders the soil profile exposed along the scarp atypical of the soil under the broader geomorphic surface (Moody and Graham, 1997). Scarps in terrain with silica-cemented soils are often nearly vertical because cementation strengthens these edges (Kendrick and Graham, 2004).

30.3.2.6 Accumulation and Redistribution of Clay

Clay-sized particles have a dominant influence on soil properties due to their large, reactive surface area. Surfaces of clay minerals play a role in water retention, nutrient storage and exchange, and precipitation of secondary minerals. The redistribution of clay is a widely observed pedogenic process, which results in a horizon of clay accumulation (Bt horizon). The development of a Bt horizon, in turn, enhances other pedogenic processes, such as the reinforcement of soil structure and the precipitation of amorphous silica.

30.3.2.6.1 Sources of Clay

Clay (inorganic particles <2 μm diameter) is produced by weathering of primary mineral grains such as feldspars, micas, pyroxenes, and amphiboles. The ions released by weathering are carried in solution to other parts of the soil profile or the landscape and precipitated as colloids such as smectite, gibbsite, kaolin, or Fe (hydr)oxides. Commonly, as primary grains are weathered, secondary minerals replace them pseudomorphically. In this case, the secondary minerals are not initially dispersed as colloids in the soil (Nahon, 1991); they enter the clay size fraction when pseudomorph grains are crushed by turbation processes (Graham and Buol, 1990). Clay contained in some parent materials, especially sediments (e.g., alluvium, colluvium, lacustrine deposits, loess) and sedimentary rocks (e.g., shale, limestone, mudstone), is simply inherited in the soils derived from them. Another significant source of clay that is particularly important in arid regions is aerosolic input (Reheis and Kihl, 1995; Simonson, 1995). In the eastern Sierra, Nevada, California, spatial variability in eolian inputs helps to explain why pedogenic clay appears to increase with moraine age while other pedogenic processes are strongly confounded by erosion of the moraines (Rossi, 2009). In this chronosequence, older moraines are located closer to the valley floor, from which most

eolian material is derived, and, therefore, the oldest moraines receive the greatest inputs of eolian-derived clays.

30.3.2.6.2 Mobilization and Transport of Clay

As the smallest particle-size fraction, clay is most susceptible to suspension in and transport by water percolating through the soil. The mobility of clay particles depends on the characteristics of the clay particles, the pore water chemistry, and the physical nature of water movement through soil. In general, the finest clay particles are more readily transported, moving even at low pore water flow rates (Kaplan et al., 1993), but even silt particles move in suspension if conditions are favorable. Clay-sized minerals with relatively strong negative charge, such as smectite, are most mobile.

Dispersion, the chemical repulsion of colloids in suspension, greatly enhances clay movement. Chemical conditions that favor dispersion in soils are those that result in an expanded diffuse double layer (Chapter 15), most notably Na-saturated clay and absence of soluble salts or partially soluble minerals (e.g., calcite, gypsum) that would increase the electrolyte concentration in solution or put Ca on exchange sites at the expense of Na. Dispersion is also enhanced by high pH because it imparts a negative charge to variable charge materials (e.g., (hydr)oxides, kaolin), which are then repulsed by each other and by the permanently negatively charged minerals. An example of this in natural systems is the effect of wood ash from forest fires, which may raise the surface soil pH above 10 (Ulery et al., 1993), causing kaolinite to disperse (Durgin and Vogelsang, 1984). Low-molecular-weight organic acids can be effective dispersive agents (Jenny and Smith, 1935; Kaplan et al., 1993, 1997; Kretzschmar et al., 1993, 1995). They complex cations in solution, thereby keeping them from flocculating clays, and they can specifically adsorb to positively charged mineral edges, preventing edge-to-face bonding with negatively charged minerals (Durgin and Chaney, 1984; Heil and Sposito, 1993a, 1993b). On the other hand, dispersion is inhibited by processes that produce stable aggregates. Thus, interparticle bonding that is enhanced by organic matter and noncrystalline inorganic compounds minimizes clay redistribution.

Mobilization and transport of clay particles by water is affected by the velocity of pore water flow and by the wetting and drying of pores. Slaking, which is the physical detachment of clay, is enhanced by increased pore water flow rates because it increases shear stress needed to detach particles from the matrix (Kaplan et al., 1993). Water flow through macropores occurs at greater velocities than micropore flow. As a result, macropore flow can move more clay and larger particles to greater depths. In fact, most clay movement is driven by macroscopic flow, even though it occurs less frequently than micropore flow. Wetting–drying cycles also enhance slaking. As a soil rewets, moving water can dislodge loose particles and carry them in suspension (Hudson, 1977). Another mechanism by which wetting–drying cycles promote clay transport is enrichment of clays with pH-dependent charge at the air–water interface in partially drained pores (Wan and Tokunaga, 2002). This partitioning results in a concentration of colloids that are readily mobilized during the next wetting cycle (DeNovio et al., 2004).

30.3.2.6.3 Deposition of Clay

Physical processes that cause a deposition of clays include immobilization by physicochemical interaction with grain surfaces or immobile air–water interfaces and straining of large clays by fine pores or thin films of water on grain surfaces (DeNovio et al., 2004). Deposition of clays may be promoted by chemical factors such as flocculation by high electrolyte concentrations as in saline or calcareous subsoils and adsorption of phyllosilicate clays with permanent negative charge to Fe and Al (hydr)oxides in acid subsoils (Jenny and Smith, 1935). Deposition of clay frequently occurs as the suspension travels into a drier part of the soil where the moving water is imbibed and retained by capillary forces. For example, when a suspension of clay flows through a macropore (Figure 30.8), water is pulled by matric forces into the soil fabric and the clay in suspension is deposited in or on the pore wall. Deposition of this type occurs in tubular, inter-pedal, and intergranular pores, and results in the characteristic parallel orientation of platy phyllosilicate clays on pore walls. Depositions of clay may be promoted by textural contrasts. Interruption of gravitational water flow as by a fine layer overlying a coarse layer leads to the deposition of colloidal material from the leaching water above the contact (Bartelli and Odell, 1960). The accumulation of clay above the contact then serves to reinforce the textural contrast, creating a positive feedback (Schaetzl and Anderson, 2005).

ψ_m decreases
(soil is drier)

1. Water flows down pore carrying clay in suspension

2. Drier subsoil is encountered

3. Matric forces pull infiltrating water out of pore, into matrix

4. Clay from suspension is plastered on pore walls

5. Phyllosilicates have *c*-axis perpendicular to pore-walls
FIGURE 30.8 Illustration of clay deposition from suspension in a tubular pore to form an oriented clay lining (i.e., clay film, channel illuviation argillan).

30.3.2.6.4 Relation to Soil Morphology

Oriented clay coatings, known as clay skins, clay films, clay linings, or argillans, are recognized visually by a discernable thickness and a darker color compared to the inside of the soil peds. Clay skins form rapidly in the laboratory (Dalrymple and Theocharopoulos, 1984) and develop within several decades in the field if pedoturbation is minimal (Graham and Wood, 1991). They are often, but not always, enriched in finer clay sizes than the soil matrix as a whole. Clay coatings are typically most abundant in subsoils (Bt horizons) but are often best preserved and expressed within the fractures of underlying saprolite or bedrock (Graham et al., 1994). They may also occur in surface horizons in which eolian deposition provides clay that is then transported by water along ped and pore surfaces (Sullivan and Koppi, 1991). In sandy, quaternary-aged soils, illuvial clay may accumulate in bands called lamellae (Rawling, 2000). The deposition of clays in lamellae has been attributed to several factors including wetting-front-drying, chemical flocculation, and sieving caused by slight variations in texture of the parent material.

Clay deposition is a strong contributor to soil structure formation by creating distinct differences between the surface and interior of peds. Deposited clays on ped surfaces are strongly oriented and can be discerned easily using a petrographic microscope and cross-polarized light. Clay skins are destroyed in soils having extensive shrink/swell activity; they are replaced by shiny slickensides or pressure faces on ped surfaces, which can be distinguished microscopically from clay skins by a different pattern of clay orientation (Nettleton et al., 1969).

30.3.2.7 Complexation and Redistribution of Fe and Al

In many soils, particularly Spodosols, dissolved organic matter plays a critical role in pedogenic processes by complexing metals, predominantly Fe and Al, in surface horizons, translocating them, and depositing them in subsoils. This process enhances a distinctive style of mineral weathering, in which chelation removes weathering products, and produces a characteristic soil morphology, epitomized by an albic horizon overlying a spodic horizon (Section 33.9).

30.3.2.7.1 Reactive Agents and Sources

Dissolved organic acids act as the carriers of metal cations. Some are simple acids derived directly from leachates of relatively fresh plant material, either from the vegetative canopy or from the leaf litter at the soil surface. Typically, the more important dissolved organic acids in soils are the byproducts of microbial decomposition of organic matter produced in the O or A horizons. They are complex, heterogeneous, relatively low-molecular-weight organic acids referred to as fulvic acids (Chapter 11). Organic acids chelate and remove cations from the surface of mineral grains. This type of weathering is very effective, since it leaves a fresh grain surface with no coatings of secondary minerals to impede solution access to the surface, a condition that inhibits further weathering. Mycorrhizal fungi also promote weathering of primary minerals in the E horizon and may transport Fe and Al to the O horizon, where concentrations of dissolved organic carbon (DOC) are highest (Lundström et al., 2000). Since organic acids keep soil solution pH below the pK_{a1} of H_2CO_3 (6.4), bicarbonate weathering is not involved in these systems (Ugolini and Spaltenstein, 1992). Iron and Al are the cations preferentially removed by organic complexation since, being relatively small cations with high valence, they form the most stable chelates (Schnitzer, 1969). At a given pH, Fe and Al will remain in solution at a much higher concentration if organically complexed.

30.3.2.7.2 Translocation and Accumulation

Chelates, forming primarily in the O and A horizons, move in solution with percolating water. During intense leaching episodes, organometal colloids, as well as dissolved metal chelates, may be flushed downward in the profile (Stoner and Ugolini, 1988). The dissolved chelates precipitate when the metal:organic carbon ratio exceeds a critical value at which all polar-bonding sites are full. The precipitation of dissolved organic matter has been studied in the laboratory, by titrating extracts from organic horizons with solutions of Fe and Al (Nierop et al., 2002). Precipitation of dissolved organic matter by Fe^{3+} occurs at lower metal:organic carbon ratios and shows less pH dependence compared to precipitation by Al^{3+} (Figure 30.9). At higher
FIGURE 30.9 Fraction of total organic C precipitated form organic horizon extract solutions as a function of: (a) the Al/C molar ratio and (b) the Fe(III)/C molar ratio, at pH 3.5, 4.0, and 4.5, illustrating the precipitation of C in response to high metal-to-C ratios. (Reprinted from Nierop, K.G.J., B. Jansen, and J.A. Verstraten. 2002. Dissolved organic matter, aluminium and iron interactions: Precipitation induced by metal/carbon ratio, pH and competition. Sci. Total Environ. 300:201–211. Copyright (2002), with permission from Elsevier.)

pH, there is less proton competition, which leads to more metal interaction with dissolved organic matter and thus more precipitation of the organic–metal complexes (Nierop et al., 2002). The pH dependence of chelate solubility may explain why translocation of Fe and Al by dissolved organic matter does not occur in calcareous soils until leaching has lowered the soil pH to 5.0 or 5.5 (Schaetzl, 1996). In the field setting, chelates may be arrested even when the metal:carbon ratio is low, by adsorbing on positively charged material, such as Fe, Al (hydr) oxides, or high metal:organic C material already precipitated. Such reactions cause polymerization of soluble low-molecular-weight compounds into insoluble forms. Chelates may also be deposited by desiccation or by aggregation in a zone of relatively high ionic strength, and low H⁺ activity, exposed negative charges. Alternatively, precipitation may occur because microbial degradation of the organic ligands releases the Fe and Al from soluble organometal complexes (Lundström et al., 2000). Spodic horizons are often identified by microscopic examination of thin sections that reveal the presence of organic and Fe (hydr)oxide-rich silt-size aggregates, many with cracked coatings indicative of postdepositional dehydration (Deconinck, 1980). Fe and Al accumulate in the spodic horizons as poorly crystalline minerals, ferrihydrite and imogolite (Lundström et al., 2000).

30.3.2.7.3 Relation to Soil Morphology

The O horizon is the major source of dissolved organic acids, which strip Fe and Al from the mineral soil as they move downward (Table 30.3). This produces the bleached E (≈albic) horizon, which exhibits the colors of the fresh primary mineral grains. The zone in which the chelates are deposited is the Bhs (or Bh, or Bs; ≈spodic) horizon. Localized intensified leaching associated with tree-throw pits or macropores (e.g., old root channels) can cause irregularities in horizon boundaries, including overthickened tongues of E horizon.

As time passes, weatherable minerals in the E horizon may become deeply pitted by dissolution while the B horizon is enriched with humus and metals. Microbial activity within the B horizon oxidizes organic C, increasing the metal:organic C ratios and releasing metals from the organic complexes to precipitate as poorly crystalline (hydr)oxides. Thus, the B horizon takes on a dark reddish brown color reflecting the humus and Fe (hydr)oxide components. Metal–humus complexes can accumulate in such a way as to produce cemented horizons. One such feature is the placic horizon, which is a thin (2–10 mm), hard, brittle, and wavy zone cemented by Fe/Mn humus. Quite commonly these features accumulate at a hydrological boundary, such as a change in particle size. A more massive cemented horizon is ortstein, which is essentially a spodic horizon cemented by Fe/Al humus. Both of these features require soil that is relatively free of physical disruption in order to form and persist. A study of carbon storage in relation to Fe and Al in grassland soils has suggested that the processes of chelation and transport of Fe and Al can occur in soils that do not develop typical spodic features (Masiello et al., 2004). In these soils, organic carbon stability was found to be strongly correlated with chelated metal ions in the A horizon and noncrystalline Fe and Al in the B horizon, suggesting a carbon storage mechanism similar to that of Spodosols. However, the morphologic expression of these processes is not visible because of the simultaneous translocation and accumulation of clays in B horizon.

30.3.2.7.4 Relation to Environmental Conditions

The process of Fe and Al translocation and accumulation is associated with specific conditions of climate and vegetation. In general, the effective climate is wet, to provide a strong leaching environment, and cool, to produce a low decomposition rate of organics. In these cool, humid environments, coniferous forests and ericaceous shrubs often prevail and are particularly effective in promoting chelation since they have acidic foliage.

As a consequence of this close relationship between climate, vegetation, and the process of Fe/Al translocation and accumulation in soils, Spodosols and similar soils are found in vast areas north of 45° latitude and at lower latitudes where high precipitation and low temperature prevail, such as coastal regions or

TABLE 30.3 Chemical Variables and Their Roles in the Complexation and Redistribution of Fe and Al in Soils

Variable	Major Role and Interaction with Other Variables	Trend, Interaction with Compartment			
		O	E and/or A	B	C
DOC	Major driving variable mobile anion, acidity source, metal complexing agent	Major source	Minor source	Major sink	No trend
pH	Low pH controlled by DOC; major variable	Lowered greatly	Lowered slightly	Rises greatly	Rises slightly
HCO₃	Controlled by pH, P_{CO_2}	Lowered	Insignificant	Insignificant	Rises significantly
Fe	Complexed and mobilized by DOC, causes DOC immobilization in B	Source	Major source	Major sink	Insignificant
Al	Complexed and mobilized by DOC, causes DOC immobilization in B; may be mobilized inorganically at low pH	Minor source	Major source	Major sink	Insignificant or minor
Basic cations	Leached in association with DOC (upper horizons) and with HCO₃⁻ (C horizons)	Major source	Source	Sink	Deep leaching (sink)

high elevations. On the other hand, Spodosols are common in warm humid regions where soils are poorly drained. Organic acids in the groundwater chelate Fe and Al, which are concentrated by the fluctuating water table to precipitate in a Bh horizon. The Bh horizons typically contain chelates but little or no free Fe as (hydr)oxides since it is reduced and leached away. Soils formed in this way have very pronounced albic and spodic horizons. They are common in the coastal plains of the southeastern United States and tropical forests such as the Orinoco basin in Brazil. The observation of close ties between organic matter stability and chelated forms of Fe and Al in moist grassland soils, without spodic properties, suggests that redistribution of Fe and Al in association of organic chelates may occur in a wider range of humid environments than previously recognized (Masiello et al., 2004).

Parent material composition is also very influential in the process of metal–humus translocation and accumulation. The process is promoted by relatively low levels of Ca, Fe, and Al. High levels of these cations prevent mobilization because a high metal:organic C complex forms quickly that is not soluble and readily translocated. Furthermore, high Ca contents promote microbial activity that decomposes soluble organics, so they are not available for chelation and leaching. As a rule, translocation of Fe– and Al–humus complexes is favored by silicic or felsic parent materials but not carbonate or mafic materials. It is further favored by coarse-textured materials (sand to coarse loamy) where surface area is low, water infiltration is rapid, and cation release is slower.

30.3.2.8 Desilication and Concentration of Resistant Oxides

Weathering of primary minerals occurs to different degrees in all soil environments. It releases highly mobile basic cations, moderately mobile $Si(OH)_4$, and relatively immobile Al^{3+} and Fe^{3+} into soil solution. The fate of these ions depends on soil leaching intensity, organic matter composition, the amount of reactive surface area, and pH. In this section, the cumulative effect of leaching on soil volume change, mineral composition, and soil fabric is discussed.

30.3.2.8.1 Leaching and Mineral Composition

In humid environments, well-drained soils lose many of the mobile constituents in a process that lowers pH and changes solution ionic composition from base cations and $Si(OH)_4$ to Al. At neutral pH, Si is more soluble than Al or Fe (Figure 30.10). In the pH range from 5 to 7, much silica can be lost by leaching. In weathered soils of the North Carolina Piedmont, 39%–75% of Si was lost relative to the parent material, but only 5%–13% of Fe and Al was lost (Oh and Richter, 2005).

Below pH 5, Al is also leached but commonly at slower rates than Si because Al can be strongly sorbed by organic matter. Usually there is enough Al in soil minerals that the pH is buffered near 5 and seldom drops to levels (<4) where Fe is dissolved due to acidity alone (Van Breemen et al., 1983). Reducing conditions are required to solubilize Fe as described
FIGURE 30.10   Mineral solubility as a function of pH.

in Section 30.3.2.9. Thus, leaching changes soil mineral stability fields in favor of minerals composed of Fe and Al and relatively small amounts of Si.

A typical soil mineral assemblage accumulated after intense weathering in a humid environment is shown in Figure 30.11.
FIGURE 30.11   Mineral distribution in an Oxisol and associated saprolite on granite. (From Eswaran, H., and W.C. Bin. 1978. A study of a deep weathering profile on granite in peninsular Malaysia. I. Physicochemical and micromorphological properties. Soil Sci. Soc. Am. J. 42:144–149. With permission of the Soil Science Society of America.)

The secondary mineral assemblage of highly weathered soils includes kaolin and sometimes hydroxy-interlayered vermiculite (containing Si and Al), gibbsite (containing Al), and hematite and goethite (containing Fe) (Lynn et al., 2002). There is also quartz that is inherited from the parent material or added by dust, and concentrated by the dissolution of other primary minerals. These minerals have low nutrient retention and supply capabilities, which means that nearly all plant nutrients must be derived from breakdown of organic matter or from atmospheric deposition. Because Si has been dramatically depleted and that remaining resides in quartz and kaolinite, these minerals are subject to weathering to a greater extent than in soils that still contain weatherable primary minerals. Even though kaolinite is considered to be a stable end product of weathering, it can decompose (and form) quite rapidly in highly leached soils (Giral-Kacmarcik et al., 1998; Ziegler et al., 2005a). Silicon is conserved by biocycling between rainforest vegetation, where it forms opal phytoliths, and soils, where it is released by weathering of the phytoliths (Lucas et al., 1993; Alexandre et al., 1997; Derry et al., 2005). The preservation of kaolin minerals in the surface horizons of some highly weathered soils may be explained by biocycling of silicon (Kleber et al., 2007).

30.3.2.8.2 Leaching and Collapse

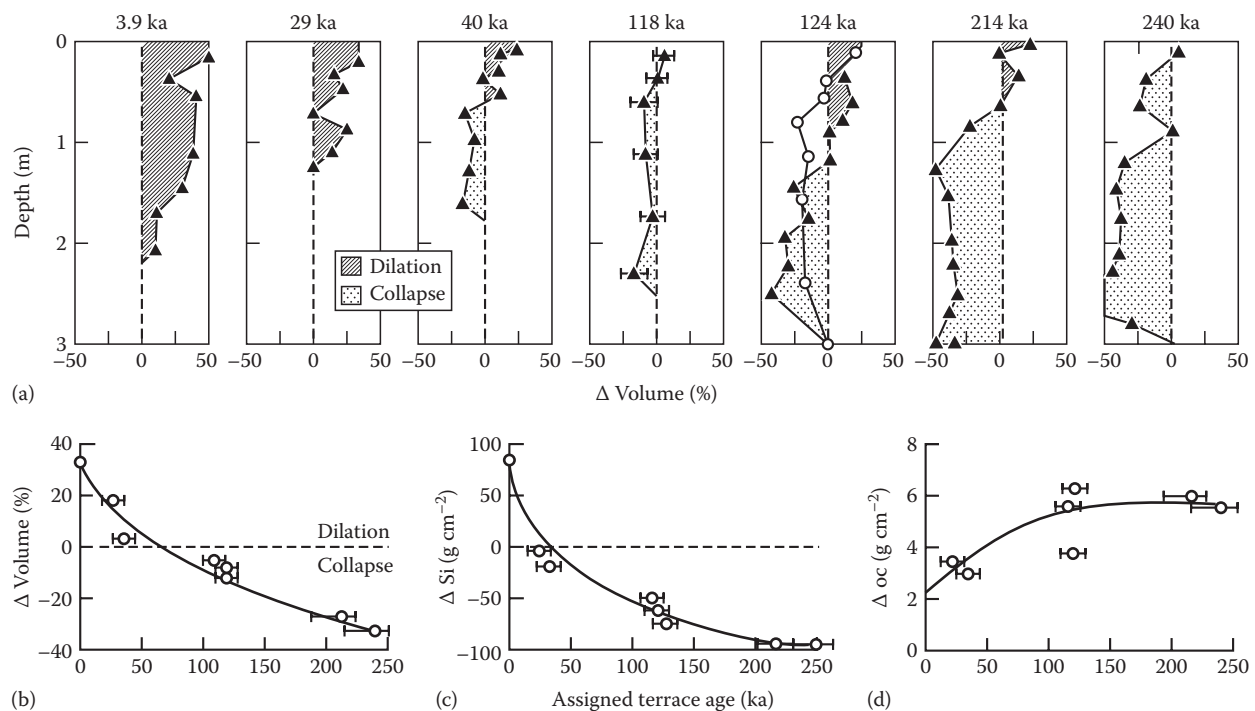
As primary rock minerals are dissolved, they commonly lose volume (Chadwick et al., 1990; Brimhall et al., 1992). This process is countered by any mass addition to soil, which will serve to expand or dilate it. Quantitative studies of leaching losses during soil formation account for these changes through the use of index minerals (or elements), which are extremely resistant to weathering (Brewer, 1964; Smeck and Wilding, 1980; Brimhall and Dietrich, 1987; Brimhall et al., 1992). Dilation is indicated when the quantity of an index element in a soil horizon is less than in the parent material and soil collapse is indicated when the opposite is true. As depicted in Figure 30.12, young soils are often dilated because accumulation of organic matter is more rapid than mineral weathering. Older soils show progressively greater collapse because mineral weathering becomes the dominant control as organic C accumulation is balanced by microbial respiration (Chadwick et al., 1994). Figure 30.12 was constructed by analyzing soils developing in beach sand on a suite of progressively older uplifted marine terraces (Brimhall et al., 1992; Merritts et al., 1992); similar pattern, of early C driven dilation followed by weathering driven collapse occur in soils on lava flows in Hawaii (Vitousek et al., 1997).


FIGURE 30.12 Parent material and soil values for bulk density and Zr are used to compute volume change that occurs as soils develop from beach sand to 240 ka on uplifted marine terraces. (a) Volume change plotted as a function of depth for each profile sampled; the 124 ka terrace was sampled in two different locations; (b) volume change integrated to the sampling depth (depth-weighted mean) to provide an average value for each profile plotted as a function of terrace age; (c) the quantity of Si leached from each profile as a summation over the soil sampling depth plotted as a function of terrace age. For these soils, base cations are leached more rapidly, and Al is not leached to a significant extent. Given the mass dominance of Si in the arkosic beach sand, Si leaching is the main control on soil collapse; (d) the quantity of organic carbon summed over the sampling depth plotted as a function of terrace age. Organic matter accumulation is the dominant factor driving early dilation and partly offsetting desilication in the older profiles. (Modified from Brimhall, G.H., O.A. Chadwick, C.J. Lewis, W. Compston, I.S. Williams, K.J. Danti, W.E. Dietrich, M.E. Power, D. Hendricks, and J. Bratt. 1992. Deformational mass-transport and invasive processes in soil evolution. Science 255:695–702. Copyright American Association for the Advancement of Science.)

30.3.2.8.3 Accumulation of Atmospherically Derived Constituents

Soils that reside on old stable geomorphic positions accumulate atmospherically transported minerals. For example, dust from Africa augments soils in the Amazon rainforest (Swap et al., 1992; Okin et al., 2004) and dust from Asia can be found in Hawaiian soils (Jackson et al., 1971; Kurtz et al., 2001). In parts of Africa and Australia, deeply weathered bauxite deposits are produced partly by the accumulation of chemically mature Fe and Al compounds that are blown in from other regions (Brimhall et al., 1988). These eolian additions are translocated into the top few meters of a deposit through macropores created by biological activity where they effectively dilate previously collapsed horizons (Brimhall et al., 1992). Below the lower limit of root growth, translocation is no longer accommodated by smaller pores in the saprolite, so leaching has led to collapse. Because these soils have accumulated eolian additions of highly weathered Fe and Al compounds, Si and basic cation losses could be overestimated when comparing soil horizons to underlying material. In contrast, when unweathered primary minerals are added to soils, it is possible that leaching losses will be underestimated. Rate of dust deposition may be similar to weathering rates, depending of mineralogy and climatic conditions (Porder et al., 2007). When weatherable dust is deposited on soils formed from resistant rock types, dust may be the main contributor to the weathering flux. On the other hand, in Hawaii, quartz-rich dust is added to soils formed on mafic bedrock, so that the dust is concentrated in the surface horizons as the bedrock parent material is broken down (Kurtz et al., 2001).

30.3.2.8.4 Relation to Soil Morphology

Horizons in the top 1–2 m of old, highly weathered soils display fine micropeds (<2 mm), which can agglomerate into larger structural units, but they rarely exceed 50 mm in diameter (van Wambeke et al., 1983). The peds are composed of strongly interbonded kaolinite and Al and Fe (hydr)oxides that have low CEC, which defines, in part, the existence of an oxic or kandic diagnostic horizon. In oxic horizons, clay films are rare both because of high aggregate stability and intense bioturbation caused by ants and termites. The soil has high microporosity within peds and relatively large interped pores, which produce excellent permeability.

In Fe-rich soils that are imperfectly drained, localized reduction and oxidation allows Fe to become mobile for short distances. Its redistribution produces localized accumulations of hematite or goethite, which appear as reddish or yellowish mottles. The location of initial deposition can be in small pores where it is thought that precipitation is favored because the chemical potential of water in close association with the solid phase is at a minimum (Tardy and Nahon, 1985), although precipitation can also occur in large pores where high P_{O_2} can lead to oxidation (Bouma, 1983). Initially, the accumulated Fe forms a weakly defined glaebule, or segregated body, that includes primary mineral grains and secondary clays as well as Fe (hydr)oxides. Slowly, the glaebule becomes more clearly defined because the engulfed minerals decompose and are replaced by Fe (hydr)oxide (Nahon, 1991). Mineral decomposition is driven by alternating oxidation and reduction of Fe, which creates acidity for enhanced hydrolysis (Brinkman, 1978). Continued growth of the glaebule produces an abrupt boundary between it and the surrounding soil matrix. In time, glaebules grow into each other producing a reticulate pattern of soil material enriched in Fe (hydr)oxides called plinthite, interspersed with less red, kaolin- and gibbsite-rich matrix. Plinthite in perennially moist soils remains soft, but under wetting and drying conditions, it can solidify into iron stone nodules or continuously cemented ferricrete. Wetting and drying can be the result of natural climate, climatic drying, erosional dissection of a plateau, or excavation of a road (Daniels et al., 1971; Nahon, 1991). There is no certain evidence on how long it takes for plinthite to harden when exposed to wetting and drying conditions.

30.3.2.9 Reduction and Oxidation Leading to Depletions and Concentrations

Environmental factors, particularly climate, topography, and the chemical and physical nature of the substratum create the drainage properties of soils, which, in turn, influence the intensity, duration, and spatial occurrence of anoxic conditions. Soils are susceptible to anoxia because O_2 is consumed by belowground microbial respiration but can only be supplied to soil pores by diffusion from the aboveground atmosphere. Soils with few macropores and many water-filled pores often consume O_2 more rapidly than it can be resupplied by diffusion. Many soils will be anoxic for short periods right after intense wetting events and the interiors of peds may be anoxic, even in otherwise well-aerated soils. When O_2 is depleted, microbially induced reduction reactions result in the dissolution of redox sensitive compounds, with the common result being an increase in their solubility, leading to selective elemental loss from the anoxic area and subsequent precipitation during exposure to higher O_2 levels. These processes leave long-lasting visible imprints on soil morphology.

30.3.2.9.1 Reactive Agents in Redox Processes

The reactive agents in redox processes include organic matter, oxygen, Fe and Mn (hydr)oxides, nitrates, sulfides and sulfates, and microbes (Chapter 14). Microbial activity is the key to reduction in soils. Microbes require a C source, supplied by solid or dissolved organic matter, and electron acceptors. In well-aerated soils, O_2 is the electron acceptor, but as it is used up, nitrates, Mn and Fe (hydr)oxides, and sulfates are used by different microbial populations. Such anaerobic conditions are usually associated with saturated or very wet soils in which there is little free pore space for the influx of O_2 from the atmosphere. Each electron acceptor compound is associated with a characteristic range of redox potentials (Chapter 14). Oxygen levels and redox potentials within a soil may show extreme variation at any given time, even on a scale of millimeters, such as from the exterior to the interior of an aggregate (Zausig et al., 1993). The behavior of nutrients that are not redox sensitive may be influenced through their interactions with redox-sensitive species. In oxidized soils

rich in Fe, considerable amounts of phosphorus can sorb to iron oxides; however, in reduced soils, the Fe sink for P is lessened and more of it is lost by leaching or remains in organic form in thickened O horizons (Miller et al., 2001).

In addition to Eh, pH also controls the form of redox sensitive species in soils. The theoretical relationship between Eh, pH, and the form of redox sensitive species can be described using stability diagrams (Vepraskas and Faulkner, 2001). However, caution is required in using these thermodynamic relationships to described real world soils, in which the soil solution composition and variation in reaction rates complicate the thermodynamic relationships expressed in a stability diagram. The effect of pH on redox reactions in soils can be observed in certain field settings. This is demonstrated by comparison of two soils with low-lying positions, seasonally high water tables, and reducing conditions on the North Carolina piedmont (McDaniel and Buol, 1991). An Ultisol formed in biotite gneiss with a very strong acid subsoil was observed to be gleyed with very little manganese, while an Alfisol formed in hornblende–epidote gneiss with a moderately acid subsoil contained concentrations of secondary Mn.

30.3.2.9.2 Oxidation of a Reduced Soil

As a wet soil drains, macropores are the first to lose water. Often shrinkage occurs during the drying of soils, so that cracks form between peds. Oxygen penetrates through the interpedal pores, root channels, macrofaunal burrows, and other macropores. In response to the higher Eh that develops within these voids, Fe and Mn (hydr)oxides precipitate from the soil solution within the matrix near the pore wall surface. Precipitation of these (hydr)oxides removes the metal from solution, thereby establishing a diffusion gradient, causing Fe^{2+} and Mn^{2+} to migrate from the still reduced soil matrix to the oxidizing zone adjacent to the macropores (Fanning and Fanning, 1989). Redox sensitive elements such as Fe and Mn often accumulate along macropores or the exterior of peds (Figure 30.13). When a fine-textured
FIGURE 30.13 Macropores (e.g., cracks) facilitate O_2 precipitation of Fe (hydr)oxides on macropore wall surfaces (e.g., ped faces). (Modified from Fanning, D.S., and M.C.B. Fanning. 1989. Soil morphology, genesis, and classification. John Wiley & Sons, New York. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.)

horizon overlies a coarse layer, Fe and Mn (hydr)oxides may be concentrated in the upper part of the coarse deposit, reflecting the oxidation of reduced Fe and Mn as they move into the larger pores of the coarse-textured deposit (D'Amore et al., 2004). Oxidized microsites within a reduced matrix, which may be more common in coarse-textured soils (D'Amore et al., 2004), provide the conditions for formation of hard aggregates of Fe and Mn (hydr)oxides, described as nodules or concretions. These features form by an initial precipitation of Fe or Mn (hydr) oxides within the microsite, which acts as a template for further precipitation. When Fe (hydr)oxides precipitate, the color is red, orange, or yellow, depending on the species of Fe (hydr)oxide formed (Chapter 22). Manganese (hydr)oxides are a strong pigment and if they are present, even at levels of tenths of a percent, a pore wall will be blackened.

30.3.2.9.3 Reduction of an Oxidized Soil

Soils that are generally well aerated and oxidized periodically become so wet that macropores are filled with water and O_2 is excluded. Spatial and temporal variability in reducing conditions occurs within saturated soils, primarily due to factors that affect the rate of microbial activity, including soil temperature and organic matter content. The length of time required for a saturated soil to develop reducing conditions is variable. On floodplain soils of the Mid-Atlantic Piedmont, it took 20 days for reducing conditions to develop when soil temperatures were <4°C, but only 2 days when the soil temperature was >9°C (Vaughan et al., 2009). This relationship between temperature and development of reducing conditions is attributed to the lower activity of soil microorganisms at low temperatures.

The spatial distribution of reducing conditions is influenced by organic matter from roots, which typically persists in old root channels and along ped faces of strongly structured soils. This organic matter provides an abundant source of C for microbes, and Fe (hydr)oxides in the soil adjacent to the macropore serve as electron acceptors and are reduced to yield Fe^{2+} in solution. At the same time, particularly in highly structured, fine-textured soils, ped interiors and soil matrix at some distance from the macropores may contain sites that are not water saturated and retain relatively high Eh conditions. In this case, Fe^{2+} mobilized from soil adjacent to the pores diffuses into the higher Eh environments within the matrix, where it precipitates as Fe (hydr)oxides (Fanning and Fanning, 1989; Vepraskas, 1996). Soil materials near the pore is the site of redox depletion and is generally a gray or white color, whereas redox concentrations of Fe (red, orange, or yellow) occur within the soil matrix (Figure 30.14). Because Mn reduction and oxidation occur at higher Eh values than Fe, Mn (hydr)oxides should also be dissolved near the water-saturated pores and precipitated within the soil matrix but not as far from the pore as the Fe.

30.3.2.9.4 Redox Soil Systems

A classic expression of the effects of varying redox conditions is found in the catena concept, where upslope soils are usually well
FIGURE 30.14 Occasional, localized reduction occurs in well-drained soils when macropores (e.g., cracks between peds) are temporarily filled with water. Fe (hydr)oxides in rims of peds are dissolved and removed or reprecipitated in more oxidized interior zones of the peds. (After Fanning, D.S., and M.C.B. Fanning. 1989. Soil morphology, genesis, and classification. John Wiley & Sons, New York. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.)

drained and oxidized, while soils at the base of the slope are, at least seasonally, poorly drained and reduced (Fanning and Fanning, 1989). As a result of these topographically induced pedochemical conditions, the upslope soils contain relatively abundant Fe (hydr)oxides and are reddish, whereas soils at the base of the slope contain few Fe (hydr)oxides, are enriched in Mn (hydr) oxides, and generally have low chroma colors (Weitkamp et al., 1996). Redox potentials in the upper slope soils are sufficiently high so that Fe (hydr)oxides are not reduced, although they are occasionally low enough to reduce Mn (hydr)oxides. Mn^{2+} is mobilized and transported to the base of the slope, where Eh is often low enough to cause reduction and loss of Fe (hydr)oxides; thus, Fe and Mn are lost from these soils, but only Mn is replaced by additions from upslope soils.

Soils that contain a slowly permeable layer, such as a dense argillic horizon, fragipan, or permafrost layer, may develop a seasonally perched water table. The resulting epiaquic conditions may not substantially deplete Fe or Mn from the soil as a whole, since there is little downward leaching. The redox sensitive elements are redistributed above and within the restrictive layer, largely by processes described above for the reduction of oxidized soils (Fanning and Fanning, 1989). An E horizon, depleted of Fe and Mn (hydr)oxides by reduction and lateral transport, may develop above the restrictive layer (McDaniel and Falen, 1994).

30.3.2.10 Mixing of Soil Materials

Processes that mix soil materials are sometimes viewed as regressive, with the idea that they oppose horizonation. In fact, while intensively mixed soils often display weak horizons, more moderate degrees of mixing can actually play a key role in forming soil horizons (Johnson et al., 1987). For example, bioturbation helps to form A horizons by mixing organic materials into the mineral soil (e.g., Graham and Wood, 1991; Figure 30.15) and various forms of mixing may obliterate rock structure, thus deepening the regolith and promoting soil formation (e.g., Heimsath et al., 1999).
FIGURE 30.15 Soil development after 41 years in lysimeter fill that has been bioturbed by earthworms (oak lysimeter) and in earthworm-free lysimeter fill (pine lysimeter). The bioturbated soils have thinner organic horizons, deeper accumulation of organic C in the mineral soil, and clay accumulation at the surface rather than in the subsoil. (From Graham, R.C., and H.B. Wood. 1991. Morphological development and clay redistribution in lysimeter soils under chaparral and pine. Soil Sci. Soc. Am. J. 55:1638–1646.)

30.3.2.10.1 Agents and Conditions

Many agents of soil mixing can be identified (Hole, 1961); however, the most widely observed include soil biota, seasonally thawed ice, and expansive clays. Mixing by soil biota, referred to as bioturbation, can be caused by both plants and animals. When trees are uprooted, large volumes of soil materials are often moved with the root system. Bioturbation by tree-uprooting is promoted

by conditions that prevent deep-rooting (e.g., shallow bedrock, hardpan, shallow water table), making the trees less wind stable (Schaetzl et al., 1989). Animals that are strong agents of bioturbation include burrowing animals (e.g., gophers, earthworms) and mound-building animals (e.g., ants, termites). Mixing by ice, or cryoturbation, is the dominant soil-forming process in permafrost-affected soils (Bockheim and Tarnocai, 1998). Cryoturbation occurs primarily in the seasonally thawed zone above the permafrost, referred to as the active layer. Mixing caused by the shrinking and swelling of clays, referred to as argilliturbation, occurs when clay-rich soils are subject to seasonal wetting and drying cycles, causing vertical cracks to open and close. Argilliturbation is most pronounced in soils rich in expansive clays, such as smectites. Though these agents work to mix the soil by different mechanisms, they are related in that they apply forces that move bulk soil materials and open up voids through which soil material can move.

30.3.2.10.2 Bioturbation

Soil material can be moved upward, downward, or laterally by bioturbation. Burrowing animals move soil upward by depositing excavated soil material at the surface. The material deposited at the surface is size fractionated to different degrees, depending on the animal. Earthworms sort the fine-earth material by ingesting more silt and clay, relative to sand (Graham and Wood, 1991; Figure 30.15), while gophers sort the coarse fragments, by moving gravels, but not cobbles, stones, or boulders (Johnson et al., 1987). Downward movement of soil material by biotic agents can occur due to backfill of macropores left open by soil organisms or by intentional transport of materials by burrowing animals. For example, some earthworms will drag leaves into their burrows, thus mixing organic horizon material into the mineral soil. Lateral transport of soil material occurs when trees are uprooted; leaving an open pit where the tree was standing and creating a mound next to the pit, where soil material slumps off of the rootwad. Mound-building animals can also be responsible for lateral movement of soil materials. For example, when gophers inhabit shallow or poorly drained soils, they redistribute the soil into mounds that are deep enough to build their burrows (Cox and Scheffer, 1991).

30.3.2.10.3 Cryoturbation

Several mechanisms of cryoturbation have been described, which may act individually or together to cause soil mixing. These mechanisms may act during freezing, thawing, or in a multistep process that involves both. Mixing due to cryostatic pressure and the frost-pull mechanism of stone movement are processes associated with freezing. The active layer freezes in fronts moving both down from the surface and up from the permafrost. The volume expansion associated with freezing causes pressure that mixes the unfrozen material between the freezing fronts (Ping et al., 2008). Frost pull occurs when the soil freezes from the surface and the primary direction of expansion is upward. Coarse fragments carried with the upward-expanding soil undergo a net upward displacement if return to their original position upon thawing is prevented by fine material infilling beneath the coarse fragment (Washburn, 1980).

Convection cell mixing is a process that is associated with the thawing of frozen soil above the permafrost. Mixing by convection cells occurs over bowl-shaped features of the permafrost table, which cause inward slumping of the thawed soil and upward displacement at the center of the bowl (Mackay, 1980). Frost wedging is a mechanism of cryoturbation that occurs due to the freeze–thaw cycle. When the active layer is frozen, thermal contraction at temperatures below −10°C causes cracks to form, and then as it thaws, melt water fills in the cracks and refreezes. Expansion of the water as it refreezes (between 4°C and 0°C) causes pressure on the surrounding soil and distortion of the land surface (Washburn, 1980).

30.3.2.10.4 Argilliturbation

Mixing by argilliturbation occurs by drying-induced shrinkage of the soil matrix and formation of desiccation cracks, followed by partial infilling of cracks from overlying horizons. The infilling material may be knocked in by biota, washed in by rain, or otherwise carried by gravity. Soils in which shrinkage increases with depth are most susceptible to these transport mechanisms because desiccation cracks become wider with depth, causing the wall to overhang the void (Hallsworth et al., 1955). When the dry, cracked soil is exposed to heavy rains or flooding, the zone beneath the cracks may wet up and expand first, causing subsoil material to be thrust toward the surface. Coarse fragments may also be moved upward, due to the swelling of clays and expansion of the soil volume upward, in the direction of least resistance. If the coarse fragments are smaller than the desiccation cracks, they may be transported back down during subsequent drying cycles. However, if the fragments are larger than the desiccation cracks they are transported upward only and accumulate at the soil surface (Johnson and Hester, 1972).

30.3.2.10.5 Relation to Soil Morphology

Mixing counteracts redistribution processes that form subsurface horizons, transports organic matter to greater depths, and causes irregularities in horizon topography. For example, in a biosequence composed of soils formed under oak, which contained earthworms, and adjacent earthworm-free soils formed under pine, only the pine soils had an argillic horizon (Graham and Wood, 1991; Figure 30.15). Mixing by the earthworms prevented illuvial clay accumulation under the oak. Mixing can also create thicker organic-rich horizons due to the infilling of animal burrows or desiccation cracks with A horizon material. In cryoturbated soils, organic matter is often observed to accumulate on top of or within the permafrost, as a result of downward transport of organic-rich materials from the surface horizons (Bockheim and Tarnocai, 1998; Bockheim, 2007; Ping et al., 2008). Examples of horizon boundaries influenced by mixing processes included swirl-like horizon patterns caused by cryostatic pressure in Gelisols (Bockheim and Tarnocai, 1998) and irregular horizon boundaries caused by up-thrust C horizon material in Vertisols (Hallsworth et al., 1955).

Processes that mix the soil may cause coarse fragments to concentrate at a certain depth in the soil. Coarse fragments too

large for transport by burrowing or mound-building animals occur in a layer beneath a mantle of finer-textured material that the animals have brought to the surface (Johnson et al., 1987). Thus, bioturbation can result in a subsurface concentration of coarse fragments, which occurs at the maximum depth of faunal activity. Argilliturbation, on the other hand, concentrates coarse fragments at the surface, in the form of a stone pavement. Stone pavement formation by argilliturbation is exemplified by Vertisols on the Channel Islands, California, which are formed in sediments deposited above bedrock, yet are observed to have an enrichment of bedrock fragments at the soil surface (Johnson and Hester, 1972). Stone pavements may also form through freeze–thaw processes in glacial landscapes (Simón et al., 2000).

Mixing often occurs in localized patches, creating heterogeneity and microtopography in soil landscapes. Microrelief created by bioturbation includes mounds built by soil fauna and pit and mound topography caused by tree throw. Pit and mound topography in Spodosols has been related to variations in horizon thickness due to more intensive leaching of the pits (Schaetzl, 1990). Microhighs and lows, referred to as gilgai relief, are a common feature of argilliturbated soils. The microhighs are often associated with soil material from below the zone of mixing that has been up-thrust toward the surface (Hallsworth et al., 1955). In cryoturbated soils, microrelief and/or sorting of coarse and fine soil materials occurs in repeated shapes, referred to as patterned ground. Examples of patterned ground included polygons, ranging from a few centimeters to a few meters in diameter, formed by frost wedging (Ping et al., 2008) and hummocks, 1–2 m in diameter, formed by slumping of the active layer as it thaws over a curved permafrost table (Mackay, 1980). In between these units, upward injection of C horizon material may occur, resulting in a sorted form of patterned ground (Vandenberghe, 1992; Ugolini et al., 2006).

30.4 From Property to Process

For convenience, specific soil-forming processes have been identified and discussed separately. This leaves the impression that one can easily interpret soil-forming processes from soil properties. To a degree this inversion can be done quite well, but care is required. Many processes occur in the same pedon simultaneously, which imprints a less than clear suite of properties. Furthermore, secondary soil-forming processes may be initiated later in soil development in response to properties developed by the primary processes. Numerous examples of such intrinsic pedogenic thresholds illustrate the complex interactions that can occur between pedogenic processes (Chadwick and Chorover, 2001; Ewing et al., 2006). Development of cemented subsurface horizons can have a strong influence on the pedogenic processes that occur in the surface horizons. For example, by decreasing rooting depth, cemented horizons in forest soils become more susceptible to bioturbation by tree-uprooting (Schaetzl et al., 1989). Altered drainage due to a cemented horizon may also dramatically change the pedogenic processes, as demonstrated in a chronosequence study in southeast Alaska, in which initial

processes of Fe and Al translocation form Spodosols with a cemented placic horizon (Ugolini and Mann, 1979). The cemented horizon impedes drainage leading to anaerobic conditions and accumulation of organic material, resulting in the formation of Histosols. Development of surface horizons that impede infiltration, such as desert pavement and vesicular horizons, may also change the pedogenic processes. These horizons cause decreased leaching, leading to accumulation of salts in the subsoil (Young et al., 2004), and increased runoff, which may eventually lead to erosion of the restrictive surface (McDonald et al., 1995). The restriction of vegetation due to stone pavement formation may also reduce the accumulation of organic matter (Simón et al., 2000). The accumulation of clay in an argillic horizon may lead to the secondary process of argilliturbation and formation of a Vertisol, especially if erosion exposes the clay-rich subsoil to surface wetting/drying cycles (Graham and Southard, 1983).

Pedogenic processes may also change over the course of soil development because of changes in the soil-forming factors over time. Soils are often polygenetic because their properties developed under different climatic conditions. Past climate change can superimpose different processes on a pedon at different times during soil formation. Soils formed in glacial deposits are subject to extreme variation in climate between glacial and interglacial periods. Glacial deposits in the Rocky Mountains have undergone phases of carbonate accumulation during interglacial periods, interrupted by cryoturbation during glacial advances (Hall, 1999). Preglacial soils in the Sierra Nevada Mountains of southern Spain include unique features that reflect the transition of pedogenic processes related to changes in climate (Simón et al., 2000). In these soils, clay films in the argillic horizon (formed during the warmer, moisture preglacial climate) have been mixed by cryoturbation during glacial periods, resulting in abundant clay fragments in the matrix. It is important to be alert to the possibility that the present set of soil properties is a composite derived from a series of temporally varying processes. Interpretation of soil processes requires as full an Earth history context as possible. Smart sampling, keen observation, and an open mind are prerequisites to successful understanding.

Soil Taxonomy

Robert J. Ahrens

Richard W. Arnold
United States Department of Agriculture

31.1 Conditions Favoring the Development of *Soil Taxonomy*

By 1960, the United States had 60 years of experience with a soil survey program, which mapped and interpreted soils in various parts of the country. Ever since the earliest mapping of areas with specialty croplands and problem saline soils, the primary purpose of the soil survey program has been to predict the consequences of alternative uses of soils.

During that time, significant events had taken place that affected the production and delivery of consistent products and services of the soil survey program. Among these were World War I, new and improved industries, enhanced energy distribution, gas motors and automobiles, mechanization of agriculture, and a shift from mainly family farms to more commercial enterprises. The Dust Bowl devastated the lives of many farmers as land degradation and unfavorable climatic conditions collided. New federal and state parks and forest reserves were established. World War II spanned the globe, followed by the Korean War. Economic reconstruction was promoted, and global markets expanded. Agriculture was also changing from a mode of unbridled production to one of increased emphasis on conservation of soil and water resources in more responsible ways. Many of these changes had impacts on the prediction of the consequences of alternative soil uses.

The model of soil changed during those times. When the soil survey started, it was perceived that soils were derived from the rocks, or from the transported materials, on which they rested, a classic geological conclusion. This concept gradually changed to that proposed by the Russian, Dokuchaev, where soils were considered to be the result of processes that were influenced by the interactions of soil-forming factors, namely, climate, biota, parent material, topography, and time. Soils were recognized as independent natural bodies worthy of study by, and for themselves, and, thus, the course of history of soil science in the United States began to change in the 1920s. Marbut promoted the independence of soils, presented his ideas of soil classification, and helped America become recognized in international affairs of soil science.

Similar climates existed over fairly large areas, as did vegetation groups such as forests and grasses, although both had microvariations. On more local scales, there were differences in parent materials and landform topography that comprised landscapes. The overlapping of the soil-forming factors in space was crucial to applying the model of soil as the result of processes that were influenced by the interactions of the soil-forming factors. Soil mappers discovered empirical relations linking sets of soil properties (generally called soil profiles) to specific landscape features, which represented soil factors. The correlation of soils with landscape segments was found to be consistent enough to be delineated on base maps and to be satisfactory for the purpose of the soil survey.

Soils, therefore, had certain predictability and so did their expected behavior. Where conditions had been the same, the soils would be the same; and where the soils were the same, those responses that depend on soil properties would be the same.

Where similar but not identical conditions or soils occurred, the soil responses would be similar, but not identical to those where the soils were identical.

Soil, which was considered to be a continuum covering the earth's terrestrial surface, could be subdivided into classes in a variety of ways, thereby creating a population or collection of individual soil bodies. Emphasis changed from thinking about the whole with loosely defined and indistinct parts to the concept in which the parts were sharply in focus and the whole was an organized collection of parts.

Locally, the individual soils were called soil types. The members of the same series, that is, soils having a similar sequence of the same kinds of horizons, were separated according to the general texture of the profile. This was a way to recognize different groups of parent material such as glacial till and loess. Initially, the soil types were grouped together into a soil series that had the same horizonation and commonality of properties. Later, soil type referred only to the texture of the surface soil and was considered as a phase of a soil series. The differences in parent materials became a basis for establishing separate series.

Mapping of soil types proceeded rapidly as there were hundreds of survey parties mapping in all parts of the country. Many new soil series were set up; however, an adequate system of correlation and classification lagged behind. It became more and more difficult to keep track of all the information being collected by the soil scientists, to compare soils from one region to another, and to communicate about soil properties and characteristics.

A number of differences in the responses to management and in land uses were found to vary geographically. Some regional variations were related to climate and age, and locally many variations were related to drainage condition and parent material. These observations supported the concept of important geographic differences and similarities and led to the need for some way of recognizing these similarities and differences. The significance of factors and factor interactions varied from region to region, and if reasonable ways to group or separate them could be found, they might serve as a basis for classification.

Over time the question about soil had changed from "How much yield can be expected from this soil with this amount of input?" to "How much input must be used on this soil to produce a given volume of produce?" This recognized that soil was dynamic and capable of modification and manipulation rather than being a static responder to management. Humans and their activities were accepted as major factors of soil formation; in fact, it was recognized that humans were the dominant influence on temporal soil quality. The changing concepts and attitudes about soil and the evolving world economic development were important contributors to the decision to develop a new soil classification system.

31.2 Recognition of Guiding Principles for a Soil Classification System

The leaders of the National Cooperative Soil Survey agreed that a classification system must serve the soil survey program of the United States. The program was undertaken for very practical reasons, namely, to identify and locate soils, and to predict the consequences of alternative uses of soils.

They indicated that a system should provide a basis for developing principles of soil genesis and behavior that would enable them to continue to provide predictions of soil behavior and responses to management and manipulation. Because soil genesis attempts to find cause and effect relationships rather than merely identifying empirical relationships, it was felt that genetic principles should serve well as a means of spatial extrapolation and to assist in interpreting soils for use (Smith, 1963).

It was clear to them that classes of a system must have real counterparts in mappable soil bodies. Some small geographic body was the entity to be classified; thus, the criteria of classification should not be applied independently of the values and variability within natural landscapes. This need to link with identifiable geographic bodies separated the practical from the purely hypothetical organization of soil property information (Cline, 1949).

It was implied that the component soil bodies in nature that were to be classified must be relevant to applied objectives. Geographic size and shape and soil attributes included within those areas were considered important for making relevant interpretations. Experience had demonstrated that this would be a problem in a classification with mutually exclusive classes; however, some of the concerns could be handled with mapping conventions.

Although the system would serve the practical uses of the soil survey, it was not implied that the classes themselves had to serve directly as the technical interpretive units. The leaders realized that valid interpretations of behavior and response likely would involve an additional step, level, or reasoning, which would rely on the known or assumed relationships between soil properties and behavior. This was also true for valid interpretations about soil genesis. It was recognized that no set of classes, or basis for groupings, or basis of subdivision, could provide units homogeneous enough for direct application to multiple objectives. Therefore, the classes had to be capable of being regrouped or subdivided as needed to satisfy different applied purposes. This was most important for the classes of the lowest category, which was the soil series (Smith, 1963).

There was agreement that a classification system must also serve to understand nature by revealing our understanding of soils as natural bodies. The accurate mapping of soils depended on this understanding. This departed from classification schemes of plants and animals where lineage relationships were assumed. This meant that science was to be basic to the process. In as much as such a system would be able to satisfy these ideas, it would be a reflection of the knowledge at a given point in time.

It was desired to have a system that could be applied uniformly by competent soil scientists. This was an important idea because it put soil scientists on an equal footing and allowed mappers to concentrate on other facets of the soil survey program. The new system would have to be objective in the sense that it should be based on properties of soils and not on beliefs of the classifier. The taxa should be defined, or recognized by observable or measurable properties selected to group soils of similar genesis, but

also capable of providing groups with similar properties, even if the genesis was uncertain or unknown. Soil genesis would be used to help select those properties that would provide useful groups of soils; however, the properties themselves would be the criteria for actual placement.

31.3 Science and Classification

Several lessons had been learned in trying to modify the 1938 classification. The concepts of some great soil groups were not clear and seemed to overlap with other groups. The methods of determining properties varied from place to place, or from time to time, and the correlations were not always certain. The mapping of soil types and soil series at the lower end of the spectrum, and the division of the pedosphere into regions and provinces and groups at the other end left an undecided middle ground with no good connections. There was great interest in not overly disturbing the thousands of soil series that had been established and used throughout the United States; yet there was a need to be able to link the series to classes in the higher categories of a classification system.

Mapping of soils and detailed laboratory studies of their properties gave rise to many consistent and repeatable correlations of soil features with landscape features. To maintain this consistency, the nature of the operations and methods used to obtain the data need to be specified and used. It is known that explanation is primarily a recognition of familiar correlations among phenomena in nature and that explanations are critical to understanding. It had been suggested that to go beyond empirical correlations to hypothesize the reasons for them will prejudice the future; therefore, there would be an effort to try to minimize using a priori principles, which determine or limit possibilities of new experiences. This meant that concepts of soil genesis would be useful to help select soil properties of interest, but that the operational character of soil facts would be used so as to not limit new experiences in the future.

There already were several thousand series considered to be classes of a lower category. They wanted some broader, more inclusive classes for making generalized maps, and an orderly organization of current understanding. It was also thought that they required flexibility to better serve other needs relying on soil information. Due to the magnitude and complexity of information, a hierarchical system of organization seemed most appropriate. For the most part, the logic of J.S. Mill as explained by Cline (1963) was followed. Some of the requirements follow.

Each category in a multicategoric system contains all members of the population of interest and is defined by abstracting the concepts that group the member classes together. Higher level categories are more abstract than those of the lower level.

The definition of a category suggests criteria that may be appropriate to separate the classes of that category. The criteria are then recognized by properties or features, which are called differentiating characteristics. These characteristics are observable or measurable properties of individuals that are grouped into a class.

Classes separated at a higher categorical level remain separated throughout the lower categories of the system. For ease of operation (placement of objects into the system), the classes are mutually exclusive, that is, without overlap. Operationally, the listing of the categories and the listing of the classes within each category need to be by priority because only a few of the characteristics of individuals are used to obtain placement within the scheme (Smith, 1983). This means that the scheme can be presented as a key or set of keys for consistent application of the definitions and the criteria (differentiating criteria).

The logic of the hierarchy represented by *Soil Taxonomy* is one of its major strengths, yet at the same time it retains the weaknesses of such organizational frameworks. The efficiency with which accessory characteristics are carried along with the differentiating ones is very powerful indeed. On the other hand, the uncertainty of the degree of accessory property relationships and the rigid class structure of the system limit the precision of statements that can be made for soils as they are observed in the field.

Recognition of a soil individual is crucial to the proper functioning of the system. Because the system was to support the soil survey, the individual had to be a recognizable geographic entity and one that could be characterized with limited sampling. The sample unit became the pedon and the soil individual became the polypedon. Their application has not been without some difficulty, which has continued even to the present.

The nomenclature of a hierarchical system is meaningful to the extent that there is consistent composition of the classes. A mnemonic scheme of phrases and combinations seemed a worthy goal. It was thought desirable to have a system of naming that would minimize previous biases and confusion and which might be translatable or usable in other languages. Consequently, roots of words from Latin and Greek and their combinations were proposed and tested. For some soil scientists the "new language" of soil classification was difficult to accept, but in retrospect was a brilliant idea.

And finally, it was agreed that the definitions must be continually tested by the nature of functioning of the soils grouped in a taxon. A taxonomy for the use of the soil survey needed to be tested by the nature of the interpretations that could be made (Smith, 1983). These interpretations included those for genesis and the mapping of soils, as well as for the behavior of soils under multiple uses.

31.4 Definitions of Categories of *Soil Taxonomy*

A category is the aggregate of classes that is formed by differentiation within a population on a single basis. A category includes the entire population; it includes all classes differentiated on one basis; it is distinguished from class that is only one part of a category; and it is definable only in terms of the basis of differentiation. In a hierarchy, the higher categories have fewer classes and they are more inclusive than the classes of the lower categories, which have accumulated attributes from all of the higher categories. Thus, high categorical levels are associated with high-level

generalizations or abstractions. These abstractions are used as the bases of differentiation; however, these ideas are expressed in terms of attributes that are assumed to be their consequences. Thus, soil attributes that are thought to be the results of such processes are the criteria used to segregate soils.

The definitions of categories, orders through series, although not stated very clearly, are intended to guide the selection and testing of properties and features used to characterize and classify soils. Soil properties that are thought to reflect processes or control processes are of great importance in this system. Although the processes of formation are influential in the selection of properties, it is the properties themselves that are used to determine the placement of soils into respective classes. The applications of quantified definitions and observations are the tests of adequacy of the theories behind this model of soil. Hence, *Soil Taxonom*y is considered a morphogenetic classification system.

31.4.1 Order

Classes at the order level are separated on the basis of properties resulting from the major processes and pathways of soil formation. Neither the genetic processes nor the courses of development are precisely known but the accepted concepts have influenced the selection of soil properties that are used to recognize and define the 12 classes currently considered. Many of the features are thought to have taken a reasonably long time to develop, are stable in a pedological sense, and are mostly static from a historical perspective.

31.4.2 Suborder

Classes at the suborder level are separated within each order on the basis of soil properties that are major controls, or reflect such controls on the current set of soil-forming processes. Most of the properties selected are dynamic such as soil moisture regime or cold soil temperatures. Other properties relate to materials or processes that retard horizon development, such as sand or alluvial sedimentation.

31.4.3 Great Group

Classes at the great group level are differentiated within each suborder on the basis of properties that constitute subordinate or additional controls, or reflect such controls on the current set of soil-forming processes. The properties selected are generally static, such as layers that retard percolation of water or root extension, but some are dynamic, such as the moisture regime where it was not a criterion at the suborder level.

31.4.4 Subgroup

Classes at the subgroup level are differentiated within each great group on the basis of properties resulting from either (1) a blending or overlapping of sets of processes in space or time that cause one kind of soil to develop from, or toward another kind of soil that has been recognized at the great group, suborder, or order level; or (2) sets of processes or conditions that have not been recognized as criteria for any class at a higher level. A third kind of subgroup fits neither (1) nor (2) but is considered to typify the central concept of the great group or simply represents what is not represented by the other subgroups.

31.4.5 Family

Classes at the family level are separated with the subgroup on the basis of properties that reflect important conditions affecting behavior or the potential for further change. Particle size, mineralogy, and soil depth are mainly capacity factors, whereas soil temperature and exchange activity are mainly intensity factors.

31.4.6 Series

Classes at the series level are separated within the family on the basis of properties that reflect relatively narrow ranges of soil-forming factors and of processes that transform parent materials into soils. Some properties are indicative of parent materials such as coarse fragments, sand or silt content, color, and horizon thickness or expression. Others reflect influences on processes such as differences in intensity or amount of precipitation, and depth to the presence or concentration of soluble compounds.

31.5 Differentiating Characteristics

The differentiating characteristics mentioned above are referred to in *Soil Taxonomy* as diagnostic horizons and characteristics or features. They are the building blocks of *Soil Taxonomy*. The diagnostic horizons and characteristics help define the criteria for the various taxa of *Soil Taxonomy*. They are also terms used by scientists to communicate the language of soil. Many soil scientists consider the concept of diagnostic horizons and features as one of the greatest contributions to soil classification.

31.5.1 Diagnostic Horizons

Diagnostic horizons are defined in the *Keys to Soil Taxonomy* (Soil Survey Staff, 2010). The intent in this chapter is not to reiterate the complete definition of the diagnostic horizons, but to provide a brief summary.

31.5.2 Diagnostic Epipedons

Diagnostic horizons that form at or near the surface are referred to as epipedons. There are eight epipedons recognized in *Soil Taxonomy*, which are briefly described below.

31.5.2.1 Anthropic Epipedon (Gr. *anthropos, Human Being*)

This is formed during long continuous use by humans, either as a place of residence (kitchen middens) or as a site for irrigated crops.

Anthropic epipedons often have the dark color of an umbric or a mollic epipedon, but were formed largely due to the actions of humans. Anthropic epipedons occur in a variety of soil orders, but are not widely recognized. Additional data and research are needed on this epipedon.

31.5.2.2 Folistic Epipedon (L. *folia*, Leaf)

This epipedon contains high amounts of organic C, but is not saturated with water for more than a few days after heavy rains. These epipedons occur mostly in cool, humid regions under forest vegetation. Folistic epipedons occur most commonly in Spodosols (see color insert) and Inceptisols (see color insert), but can occur in other orders.

31.5.2.3 Histic Epipedon (Gr. *histos*, Tissue)

This is 20–60 cm thick and contains high amounts of organic C. It differs from the folistic epipedon in that it is commonly saturated with water for long periods. Histic epipedons can occur in many soil orders.

31.5.2.4 Melanic Epipedon (Gr. *melas*, melan-, Black)

This is a thick, black horizon that contains high concentrations of organic C and short-range order minerals or Al–humus complexes. It commonly occurs in areas associated with a volcanic influence under forest vegetation. Melanic epipedons are associated with Andisols (see color insert for Andisol and Andisol (2)).

31.5.2.5 Mollic Epipedon (L. *mollis*, Soft)

This is a relatively thick, dark-colored, humus-rich surface horizon in which divalent cations are dominant on the exchange complex. It forms from the underground decomposition of organic residues, chiefly grasses, although particularly in ustic soil moisture regimes occur under a variety of vegetation, including shrubs and trees. Mollic epipedons have good structure and porosity and are associated with some of the richest agricultural soils in the world. Mollic epipedons are most commonly associated with Mollisols (see color insert for Mollisol and Mollisol (2)); they very rarely occur in other soil orders.

31.5.2.6 Ochric Epipedon (Gr. *ochros*, Pale)

This fails to meet the definition of any of the other diagnostic epipedons. It can be light colored, thin and dark colored, or even thin with high amounts of organic C. It has few or no accessory characteristics, but was defined to serve as a means of placing a name on the surface horizons that failed the criteria of any of the other seven epipedons. Ochric epipedons can occur in a variety of soil orders.

31.5.2.7 Plaggen Epipedon (Ger. *Plaggen*, Sod)

Plaggen epipedons are rare and occur mostly in Europe where in medieval times sod or other materials were used for bedding livestock, and the manure was spread on cultivated fields. The gradual additions of bedding materials raised the level of the fields. The plaggen epipedon is associated with Inceptisols.

31.5.2.8 Umbric Epipedon (L. *umbra*, Shade, Hence Dark)

Umbric epipedons resemble mollic epipedons but form largely under a forest vegetation and have a lower natural fertility (base saturation) than the mollic epipedon. The umbric epipedon is most commonly associated with Inceptisols, Andisols, Alfisols (see color insert), Ultisols (see color insert for Ultisol and Ultisol (2)), and Gelisols (see color insert).

31.5.3 Diagnostic Subsurface Horizons

The subsurface horizons form below the surface, but can be at or near the surface in eroded soils. Brief descriptions follow.

31.5.3.1 Agric Horizon (L. *ager*, Field)

This is an illuvial horizon, which has formed under cultivation and contains significant amounts of illuvial silt, clay, and humus. This horizon is relatively rare, or perhaps not readily recognized, and is often more associated with old world agriculture. Agric horizons are associated with Alfisols.

31.5.3.2 Albic Horizon (L. *albus*, White)

This is an eluvial horizon 1.0 cm or more thick with a color that is largely determined by the color of the primary sand and silt grains, rather than the color of their coatings. The clay and Fe oxides have been removed by pedogenesis. Albic horizons are most commonly associated with Spodosols, Alfisols, Ultisols, and Mollisols.

31.5.3.3 Argillic Horizon (L. *argilla*, White Clay)

An argillic horizon is commonly a subsurface horizon with a significantly higher content of phyllosilicate clay than the overlying horizon. There is also evidence of clay illuviation. Argillic horizons occur on stable landscapes and are most commonly associated with Alfisols, Ultisols, Aridisols (see color insert), and Mollisols.

31.5.3.4 Calcic Horizon (L. *calcis*, Lime)

This is an illuvial horizon in which secondary $CaCO_3$ has accumulated to a significant extent. In arid environments, precipitation is insufficient to move carbonates to great depths. In soils with water near the surface, capillary rise, evaporation, and transpiration concentrate $CaCO_3$ toward the surface. Calcic horizons occur in Aridisols, Alfisols, Andisols, Mollisols, Inceptisols, Vertisols (see color insert for Vertisol and Vertisol (2)), and Gelisols.

31.5.3.5 Cambic Horizon (L. *cambiare*, to Exchange)

The cambic horizon forms as a result of physical alterations, chemical transformations, accumulations, removals, or a combination of these processes. They are commonly identified by structure and a higher clay content, redder hue, or higher chroma than an overlying horizon. Cambic horizons are most commonly associated with Inceptisols, but they can occur in Aridisols, Mollisols, Vertisols, Andisols, and Gelisols.

31.5.3.6 Duripan (L. *durus*, Hard)

A duripan is cemented by illuvial silica. Duripans limit the downward growth of roots and movement of water. They are most commonly associated with the Aridisols, but are known to occur in Alfisols, Mollisols, Andisols, Inceptisols, Spodosols, and Vertisols.

31.5.3.7 Fragipan (L. *fragilis*, Brittle, and Pan)

This is a subsurface horizon that is noncemented, but restricts the entry of water and roots into the soil matrix. Fragipans most commonly are associated with Ultisols, Alfisols, Spodosols, and Inceptisols.

31.5.3.8 Glossic Horizon (Gr. *glossa*, Tongue)

The glossic horizon develops as a result of the degradation of an argillic, kandic, or natric horizon. Clay and Fe oxides are removed starting from the exterior of the peds. These horizons are transitional from argillic, natric, and kandic horizons to albic horizons. Glossic horizons occur most commonly in the Alfisols and Ultisols.

31.5.3.9 Gypsic Horizon (L. *gypsum*)

This is an illuvial horizon in which secondary gypsum has accumulated to a significant extent. Most gypsic horizons occur in arid environments where the parent materials are rich in gypsum. In soils with groundwater close to the surface, gypsum can accumulate by capillary rise, evaporation, and transpiration. Gypsic horizons most commonly occur in the Aridisols, but a few Inceptisols, Vertisols, and Gelisols also have gypsic horizons.

31.5.3.10 Kandic Horizon (Modified from Kandite)

This is a subsurface horizon with a significantly higher content of clay than an overlying horizon. Kandic horizons are dominated by low activity clays (1:1) and, therefore, have low cation exchange capacity (CEC). Kandic horizons occur in the Ultisols and Oxisols (see color insert for oxisol and oxisol (2)).

31.5.3.11 Natric Horizon (L. *natrium*, Sodium)

The natric horizon has all the characteristics of the argillic horizon (significant clay increase) and, in addition, has an accumulation of Na. Sodium adversely affects the physical properties of a soil. Of the soil orders, natric horizons are most commonly associated with the Aridisols, but they also occur in the Alfisols and Mollisols and to a very limited extent in the dry Gelisols.

31.5.3.12 Ortstein

Ortstein is a cemented horizon that consists of complexes of Al and organic matter with or without Fe (spodic materials). Ortstein limits root growth and the downward movement of water. Ortstein occurs in Spodosols.

31.5.3.13 Oxic Horizon (F. *oxide*)

This is a subsurface horizon of sandy loam or a finer texture with a low CEC and low amount of weatherable minerals. Oxic horizons occur in old, weathered soils or soils derived from highly weathered parent materials. Oxic horizons occur in Oxisols.

31.5.3.14 Petrocalcic Horizon (Gr. *petra*, Rock and Calcic)

This is cemented or indurated by $CaCO_3$ or Ca and Mg carbonates. It is a barrier to roots and the downward movement of water. Petrocalcic horizons are most commonly associated with the Aridisols, but also occur in the Alfisols, Mollisols, Vertisols, and Inceptisols.

31.5.3.15 Petrogypsic Horizon (Gr. *petra*, Rock and Gypsic)

This is cemented or indurated by gypsum. It is a barrier to roots and downward movement of water. Petrogypsic horizons are most commonly associated with Aridisols.

31.5.3.16 Placic Horizon

This is a thin (<25 mm), dark-colored horizon that is cemented by either Mn or Fe and Mn and organic matter. Commonly, they occur in moist, cool climates and are associated with the Spodosols and Inceptisols.

31.5.3.17 Salic Horizon (L. *sal*, Salt)

This is an accumulation of salts that are more soluble than gypsum in water. Many plants are intolerant of high concentrations of salt. Most salic horizons are associated with the Aridisols; a few occur in the drier Gelisols.

31.5.3.18 Sombric Horizon (F. *sombre*, Dark)

This is an illuvial horizon that contains humus that is not associated with Al nor dispersed by Na. It is largely confined to the cool, moist soils of high plateaus or mountains of the tropics and subtropics. Sombric horizons are associated with Inceptisols, Oxisols, and Ultisols.

31.5.3.19 Spodic Horizon (Gr. *spodos*, Wood Ash)

This is an illuvial horizon that contains active amorphous materials composed of organic matter and Al with or without Fe. Spodic horizons are associated with Spodosols.

31.5.3.20 Sulfuric Horizon (L. *sulfur*, Sulfur)

The sulfuric horizon forms when sulfide rich and organic materials are oxidized as a result of drainage, most commonly artificial. Sulfuric horizons are toxic to most plants. They occur in Entisols (see color insert), Histosols (see color insert), and Inceptisols.

31.5.4 Other Diagnostic Soil Characteristics

The diagnostic soil characteristics are features of the soil that are used repeatedly in *Soil Taxonomy*.

Abrupt textural change is a considerable increase in clay within a short distance, a very important feature used to help predict water movement in soils.

Albic materials are light-colored soil materials that reflect the color of the primary sand and silt particles rather than the color of the coatings.

Andic soil properties result from the presence of significant amounts of allophane, imogolite, ferrihydrite, or Al–humus complexes.

Anhydrous conditions refer to the moisture condition of soils in very cold deserts and other areas that have dry permafrost.

Aquic conditions arise in soils that currently experience continuous or periodic saturation and reduction. The presence of these features is indicated by redoximorphic features. There are several types of saturation: Episaturation describes a perched water table, endosaturation describes a groundwater table, and anthraquic saturation describes controlled flooding such as that used to grow rice and cranberries.

Coefficient of linear extensibility (COLE) is the ratio of the difference between the moist and dry lengths of a clod to its dry length. COLE is used to determine the shrink/swell potential of a horizon.

Cryoturbation (frost churning) is the mixing of the soil matrix that results in irregular or broken horizons.

Densic contact occurs between soil and densic materials and is a barrier to roots.

Densic materials are noncemented, relatively unweathered, mostly earthy materials such as till, volcanic mudflows, and noncemented rocks.

Durinodes are cemented to indurated nodules with SiO_2, presumably opal and microcrystalline forms of silica.

Fragic soil properties are similar to a fragipan, but do not have the required thickness or volume for a fragipan.

Gelic materials are soil materials that show evidence of cryoturbation or ice segregation in the active layer.

Glacic layer is massive ice in the form of ice lenses and wedges.

Identifiable secondary carbonates refer to translocated authigenic $CaCO_3$ that has been precipitated in place from the soil solution rather than precipitated in place from the parent material.

Interfingering of albic materials refers to albic materials that penetrate 5 cm or more into an underlying horizon.

Lamellae are thin (<7.5 cm) illuvial horizons that contain evidence of illuvial clay and occur only in coarse-textured soils.

Linear extensibility is the product of the thickness (cm) multiplied by the COLE of the soil layer in question and is used to predict shrink and swell.

Lithic contact occurs between soil and a coherent underlying material that is in a strongly or more cemented class. Lithic contacts occur at the boundary between soil and hard bedrock.

Lithologic discontinuities are significant differences in particle-size distribution or mineralogy that represent differences in lithology of a soil.

N value is used to predict if a soil can support loads and to the degree of subsidence after drainage.

Paralithic contact occurs between soil and paralithic materials (defined below) such as between soil and unconsolidated or weathered bedrock.

Paralithic materials are relatively unaltered (by pedogenesis) materials that are in a moderately or less cemented class.

Permafrost refers to soil material that remains below 0°C for 2 or more years in succession.

Petroferric contact is a boundary between soil and a continuous layer of indurated material in which Fe is an important cement and organic matter is either absent or present in trace amounts.

Plinthite is an Fe-rich, humus-poor material that irreversibly hardens when exposed to wetting and drying, especially if heated by the sun.

Resistant minerals refer to durable minerals in the 0.02–2.0 mm fraction, such as quartz, zircon, etc.

Slickensides are polished and grooved surfaces produced by one mass sliding past another. They are a feature of soils with a high capacity to shrink and swell.

Spodic materials are illuvial, amorphous materials composed of organic material and aluminum with or without iron.

Sulfidic materials contain oxidizable sulfur compounds.

31.5.5 Soil Moisture and Temperature Regimes

Soil Taxonomy is unique among many systems used to classify soils because it recognizes the temperature of a soil and the moisture status of a soil over time. Both temperature and moisture are important properties of the soil and convey essential information about soils. Because complete definitions for the soil moisture and temperature regimes can be found in the *Keys to Soil Taxonomy* (Soil Survey Staff, 2010), only brief descriptions are presented here.

31.5.5.1 Soil Moisture Regimes

For most soil orders, moisture regime is used to determine placement of a soil at the suborder level.

Aquic moisture regime signifies a reducing regime virtually free of dissolved O_2 from saturation with water. Most soils that have an aquic moisture regime are not saturated with water to the soil surface year round.

Aridic (torric) moisture regime applies to soils that commonly occur in arid climates and are dry in all parts more than half the time during the growing season and moist in some or all parts for less than 90 consecutive days during the growing season.

Udic moisture regime applies to soils that occur in climates with well-distributed rainfall or sufficient summer rain so that rainfall plus stored moisture equals or exceeds the amount of evaporation.

Ustic moisture regime is moister than aridic and drier than udic. The concept of ustic is one of limited moisture, but at least some moisture at a time when conditions are suitable for plant growth.

Xeric moisture regime applies to soils that occur in climates with cool, moist winters and warm, dry summers.

Perudic moisture regime applies to soils that occur in areas where precipitation exceeds evaporation in all months when the soil is not frozen.

Order	Suborder	Great Group	Subgroup	Family	Series
Aridisols	Argids	Calciargids	Ustic Calciargids	Fine-loamy, mixed, superactive, mesic	Barx "Clovis, Flaco".

31.5.5.2 Soil Temperature Regimes

The following soil temperature regimes are based on the mean annual temperature of a soil measured at 50 cm or at a lithic, paralithic, or densic contact, whichever is shallowest.

Cryic soil temperature regime applies to soils that have a mean annual soil temperature of <8°C, but no permafrost and a summer temperature cooler than soils in a frigid regime.

Frigid soil temperature regime applies to soils that have a mean annual soil temperature of <8°C.

Mesic temperature regime applies to soils that have a mean annual soil temperature of 8°C but <15°C.

Thermic temperature regime applies to soils that have a mean annual soil temperature of 15°C but <22°C.

Hyperthermic temperature regime applies to soils that have a mean annual soil temperature of 22°C.

When the difference between mean summer and winter soil temperatures is less than 6°C, *iso* is added to the name. *isofrigid*, *isomesic*, *isothermic*, and *isohyperthermic* are the only classes used. Soil temperature is most commonly used at the family level in *Soil Taxonomy*.

31.6 Categories of *Soil Taxonomy*

The information that follows is largely from the second edition of *Soil Taxonomy* (Soil Survey Staff, 1999). The diagnostic horizons and characteristics help define the categories of *Soil Taxonomy*.

A category of *Soil Taxonomy* is a set of classes that is defined approximately at the same level of generalization or abstraction and includes all soils. There are six categories or levels in *Soil Taxonomy*. In order of decreasing rank and increasing number of differentiae and classes, the categories are order, suborder, great group, subgroup, family, and series.

The nomenclature of *Soil Taxonomy* is based on the following premises: Each taxon requires a name if it is to be used in speech; a good name is short, easy to pronounce, and distinctive in meaning; a name is connotative, that is, capable of mnemonic attachment to the concept of the thing itself (Heller, 1963); it is useful if the name of a taxon indicates its position in the classification, if similarities in important properties are reflected by similarities in names, if the mnemonic attachments hold in many languages, and if the name fits into many languages without translation.

The name of each taxon above the category of series indicates its class in all categories of which it is a member. The name of a soil series indicates only the category of series. Thus, a series name may be recognized as a series, but one cannot tell from the name to what order, suborder, and so on, it belongs.

Table 31.1 gives a few examples of names of taxa in each category from order to series. Because of the system for assigning names and because most formative elements carry the same meaning in any combination, a name can convey a great deal of information about a soil.

31.7 Recognition of the Categories

31.7.1 Orders

The name of each order ends in sol (L. *solum*, soil) with the connecting vowel *o* for Greek roots and *i* for other roots. Each name of an order contains a formative element that begins with the vowel immediately preceding the connecting vowel and ends with the last consonant preceding the connecting vowel. In the order name, Entisol, the formative element is *ent*. In Aridisol, it is *id*. These formative elements are used as endings for the names of suborders, great groups, and subgroups. Thus, the names of all taxa higher than the series that are members of the Entisol order end in *ent* and can be recognized as belonging to the order of Entisol. Names ending in *id* are names of taxa belonging to the order of Aridisols. Table 31.2 lists all the soil orders and their formative elements.

31.7.2 Suborders

Names of suborders have exactly two syllables. The first syllable connotes something of the diagnostic properties of the soils or the soil moisture regime. The second is the formative element from the name of the order. Thirty formative elements

TABLE 31.2   Formative Elements in Names of Soil Orders in *Soil Taxonomy*

Formative Element in Name	Name of Order	Derivation of Formative Element	Pronunciation of Formative Element
Alf	Alfisol	Meaningless syllable	Pedalfer
And	Andisol	Modified from ando	Ando
Id	Aridisol	L. *aridus*, dry	Arid
Ent	Entisol	Meaningless syllable	Recent
El	Gelisol	L. *gelare*, to freeze	Jell
Ist	Histosol	Gr. *histos*, tissue	Histology
Ept	Inceptisol	L. *inceptum*, beginning	Inception
Oll	Mollisol	L. *mollis*, soft	Mollify
Ox	Oxisol	F. *oxide*, oxide	Oxide
Od	Spodosol	Gr. *spodos*, wood ash	Odd
Ult	Ultisol	L. *ultimus*, last	Ultimate
Ert	Vertisol	L. *verto*, turn	Invert

TABLE 31.3 Formative Elements in Names of Suborders in *Soil Taxonomy*

Formative Element	Derivation	Connotation
Alb	L. *albus*, white	Presence of albic horizon
Anth	Gr. *anthropos*, human	Modified by humans
Aqu	L. *aqua*, water	Aquic conditions
Ar	L. *arare*, to plow	Mixed horizon
Arg	L. *argilla*, white clay	Presence of argillic horizon
Cal	L. *calcis*, lime	Presence of calcic horizon
Camb	L. *cambiare*, to exchange	Presence of cambic horizon
Cry	Gr. *kryos*, icy cold	Cold
Dur	L. *durus*, hard	Presence of duripan
Fibr	L. *fibra*, fiber	Least decomposed stage
Fluv	L. *fluvius*, river	Floodplain
Fol	L. *folia*, leaf	Mass of leaves
Gel	L. *gelare*, to freeze	Jell
Gyps	L. *gypsum*, gypsum	Presence of gypsic horizon
Hapl	Gr. *haplos*, simple	Minimum horizon development
Hem	Gr. *hemi*, half	Intermediate stage of decomposition
Hist	Gr. *histos*, tissue	Presence of organic materials
Hum	L. *humus*, earth	Presence of organic matter
Orth	Gr. *orthos*, true	The common ones
Per	L. *per*, throughout time	Perudic moisture regime
Psamm	Gr. *psammos*, sand	Sandy texture
Rend	Modified from rendzina	High carbonate content
Sal	L. *sal*, salt	Presence of salic horizon
Sapr	Gr. *saprose*, rotten	Most decomposed stage
Torr	L. *torridus*, hot and dry	Torric moisture regime
Turb	L. *turbidis*, disturbed	Presence of cryoturbation
Ud	L. *udus*, humid	Udic moisture regime
Ust	L. *ustus*, burnt	Ustic moisture regime
Vitr	L. *vitrum*, glass	Presence of glass
Xer	Gr. *xeros*, dry	Xeric moisture regime

(Table 31.3) are used with the 12 formative elements from names of the orders to make names of over 65 suborders. The suborder of Entisols that has aquic conditions throughout is called Aquents (L. *aqua*, water, plus *ent* from Entisol). The formative element *aqu* is used with this meaning in 9 of the 12 orders. The suborder of Entisols that consists of very young sediments is called Fluvents (L. *fluvius*, river, plus *ent* from Entisol).

31.7.3 Great Groups

The name of a great group consists of the name of a suborder and a prefix that consists of one or two formative elements suggesting something of the diagnostic properties. Names of great groups, therefore, have three or four syllables and end with the name of a suborder. Fluvents that have a cryic temperature regime are called Cryofluvents (Gr. *kryos*, icy cold, plus fluvent). Fluvents that have a torric moisture regime are called Torrifluvents (L. *torridus*, hot and dry). The formative elements for the great groups are listed in Table 31.4.

31.7.4 Subgroups

The name of a subgroup consists of the name of a great group modified by one or more adjectives. The adjective, typic, represents in some instances what is thought to typify the great group and in other instances, typic subgroups simply do not have any of the characteristics used to define the other subgroups in a great group. Each typic subgroup has, in clearly expressed form, all the diagnostic properties of the order, suborder, and great group to which it belongs. Typic subgroups also have no additional properties indicating a transition to another great group. Typic subgroups are not necessarily the most extensive subgroup of a great group.

Intergrade subgroups are those that belong to one great group but that have some properties of another order, suborder, or great group. They are named by using the adjectival form of the name of the appropriate taxon as a modifier of the great group name. Thus, the Torrifluvents that have some of the properties or properties closely associated with Vertisols are called Vertic Torrifluvents. Vertic Torrifluvents have some of the properties of Vertisols superimposed on the complete set of diagnostic properties of Torrifluvents.

Extragrade subgroups are those that have important properties that are not representative of the great group but that do not indicate transitions to any other known kind of soil. They are named by modifying the great group name with an adjective that connotes something of the nature of the aberrant properties. Thus, a Cryorthent that has bedrock that is at least strongly cemented within 50 cm of the mineral soil surface is called a Lithic Cryorthent (lithic, Gr. *lithos*, stone). This subgroup is listed as an example in Table 31.5.

31.7.5 Families

Names of families are polynomial. Each consists of the name of a subgroup and descriptive terms, generally three or more, to indicate the particle-size class (or combinations thereof, if strongly contrasting), the mineralogy (26 classes), the cation exchange activity (4 classes), the calcareous and reaction (4 classes), the temperature (8 classes), and, in a few families, depth of soil (3 classes), rupture resistance (2 classes), and classes of coatings and classes of cracks (3 classes). Names of most families have three to five descriptive terms that modify the subgroup name, but a few have only one or two and a few as many as six. An example given in Table 31.1 is a family of fine-loamy (particle size), mixed (mineralogy), superactive (cation exchange activity), and mesic (soil temperature) Ustic Calciargids.

31.7.6 Series

Names of series as a rule are abstract place names. The name usually is taken from a place near where the series was first recognized. It may be the name of a town, a county, or some local feature. Some series have coined names while many have been carried over from earlier classifications with some having been

TABLE 31.4 Formative Elements in Names of Great Groups in *Soil Taxonomy*

Formative Element	Derivation	Connotation
Acr	Gr. *akros*, at the end	Extreme weathering
Al	Modified from aluminum	High aluminum, low iron
Alb	L. *albus*, white	Presence of an albic horizon
Anhy	Gr. *anhydros*, waterless	Very dry
Anthr	Gr. *anthropos*, human	An anthropic epipedon
Aqu	L. *aqua*, water	Aquic conditions
Arg	L. *argilla*, white clay	Presence of an argillic horizon
Calc	L. *calcis*, lime	A calcic horizon
Cry	Gr. *kryos*, icy cold	Cold
Dur	L. *durus*, hard	A duripan
Dystr (Dys)	Gr. *dys*, ill; dystrophic, infertile	Low base saturation
Endo	Gr. *endo*, within	Implying a groundwater table
Epi	Gr. *epi*, on, above	Implying a perched water table
Eutr (Eu)	Gr. *eu*, good; eutrophic, fertile	High base saturation
Ferr	L. *ferrum*, iron	Presence of iron
Fibr	L. *fibra*, fiber	Least decomposed stage
Fluv	L. *fluvius*, river	Floodplain
Fol	L. *folia*, leaf	Mass of leaves
Frag	L. *fragilis*, brittle	Presence of fragipan
Fragloss	Compound of fra(g) and gloss	See Frag and Gloss
Fulv	H. *fulvus*, dull	Dark brown color, presence of organic C
Gel	L. *gelare*, to freeze	Jell
Glac	L. *glacialis*, icy	Ice lenses or wedges
Gyps	L. *gypsum*, gypsum	Presence of gypsic horizon
Gloss	Gr. *glossa*, tongue	Presence of glossic horizon
Hal	Gr. *hals*, salt	Salty
Hapl	Gr. *haplos*, simple	Minimum horizon
Hem	Gr. *hem*, half	Intermediate stage of decomposition
Hist	Gr. *histos*, tissue	Presence of organic materials
Hum	L. *humus*, earth	Presence of organic matter
Hydr	Gr. *hydor*, water	Presence of water
Kand	Modified from kandite	1:1 layer silicates
Luv	Gr. *louo*, to bath	Illuvial
Melan	Gr. *melasanos*, black	Black, presence of organic C
Molli	L. *mollis*, soft	Presence of a mollic epipedon
Natr	L. *natrium*, sodium	Presence of a natric horizon
Pale	Gr. *paleos*, old	Excessive development
Petro	Gr. *petra*, rock	A cemented horizon
Plac	Gr. *plax*, flat stone	Presence of a thin pan
Plagg	Ger. *plaggen*, sod	Presence of a plaggen epipedon
Plinth	Gr. *plinthos*, brick	Presence of plinthite
Psamm	Gr. *psammos*, sand	Sand texture
Quartz	Ger. *quart*, quartz	High quartz content
Rhod	Gr. *rhodon*, rose	Dark red color
Sal	L. *sal*, salt	Presence of a salic horizon
Sapr	Gr. *saprose*, rotten	Most decomposed stage
Somb	F. *sombre*, dark	Presence of sombric horizon
Sphagn	Gr. *sphagnos*, bog	Presence of sphagnum
Sulf	L. *sulfur*, sulfur	Presence of sulfides or their oxidation products
Torr	L. *torridus*, hot	Tonic moisture regime and dry
Ud	L. *udus*, humid	Udic moisture regime
Umbr	L. *umbra*, shade	Presence of an umbric horizon
Ust	L. *ustus*, burnt	Ustic moisture regime
Verm	L. *vermes*, worm	Wormy or mixed by animals
Vitr	L. *vitrum*, glass	Presence of volcanic glass
Xer	Gr. *xeros*, dry	Xeric moisture regime

TABLE 31.5 Adjectives in Names of Extragrades in *Soil Taxonomy* and Their Meaning

Adjective	Derivation	Connotation
Abruptic	L. *abruptum*, torn off	Abrupt textural change
Aeric[a]	Gr. *aerios*, air	Aeration
Albic	L. *albus*, white	Presence of an albic horizon
Alic	Modified from aluminum	High Al^{3+} status
Anionic	Gr. *anion*	Positively charged colloid
Anthraquic	Gr. *anthropos*, human and L. *aqua*, water	Controlled flooding
Anthropic	Gr. *anthropos*, human	An anthropic epipedon
Arenic	L. *arena*, sand	Sandy between 50 and 100 cm thick
Calcic	L. *calcis*, lime	Presence of a calcic horizon
Chromic	Gr. *chroma*, color	High chroma
Cumulic	L. *cumulus*, heap	Thickened epipedon
Durinodic	L. *durus*, hard	Presence of durinodes
Dystic	Gr. *dys*, ill	Low base status
Eutric	Gr. *eu*, good; eutrophic, fertile	High base status
Fragic	L. *fragilis*, brittle	Presence of fragic properties
Glacic	Gr. *glacialis*, icy	Presence of ice lenses or wedges
Glossic	Gr. *glossa*, tongue	Tongued horizon boundaries
Grossarenic	L. *grossus*, thick; *arena*, sand	Thick, sandy layer
Gypsic	L. *gypsum*, gypsum	Presence of a gypsic horizon
Halic	Gr. *hals*, salt	Salty
Humic	L. *humus*, earthy	Presence of organic matter
Hydric	Gr. *hydor*, water	Presence of water
Kandic	Modified from kandite	Presence of 1:1 layer silicates
Lamellic	L. *lamella*, dim	Presence of lamellae
Leptic	Gr. *leptos*, thin	A thin soil
Limnic	Gr. *limn*, lake	Presence of a limnic layer
Lithic	Gr. *lithos*, stone	Presence of a shallow lithic contact
Natric	L. *natrium*, sodium	Presence of sodium
Nitric	Modified from *nitron*	Presence of nitrate salts
Ombroaquic	Gr. *ombros*, rain; L. *aqua*, water	Surface wetness
Oxyaquic	Oxy representing oxygen and aquic	Aerated
Pachic	Gr. *pachys*, thick	A thick epipedon
Petrocalcic	Gr. *petra*, rock; L. *calcis*, lime	Presence of a petrocalcic horizon
Petroferric	Gr. *petra*, rock; L. *ferrum*,, iron	Presence of a petroferric contact (ironstone)
Petrogypsic	Gr. *petra*, rock; L. *gypsum*, gypsum	Presence of a petrogypsic horizon
Petronodic	Gr. *petra*, rock; L. *nodulus*, a little knot	Presence of concretions and/or nodules
Placic	Gr. *plax*, flat stone	Presence of a thin pan (placic horizon)
Plinthic	Gr. *plinthos*, brick	Presence of plinthite
Rhodic	Gr. *rhodon*, rose	Dark red color
Ruptic[a]	L. *ruptum*, broken	Intermittent or broken horizons
Sodic	Modified from sodium	Presence of sodium
Sombric	F. *sombric*, dark	Presence of sombric horizon
Sulfic	L. *sulfur*, sulfur	Presence of sulfides or their oxidation products
Terric	L. *terra*, earth	A mineral substratum
Thapto(ic)[a]	Gr. *thapto*, buried	A buried soil
Ultic	L. *ultimus*, last	Low base status
Umbric	L. *umbra*, shade	Presence of umbric epipedon
Xanthic	Gr. *xanthos*, yellow	Yellow color

[a] Not strictly an extragrade. Name used to indicate a special departure from the typic subgroup.

in use since 1900. The name of a series carries no meaning to people who have no other source of information about the soils in it. There are over 21,000 soil series currently recognized in the United States.

The Barx, Clovis, and Flaco series (Table 31.1) are three members of the fine-loamy, mixed, superactive, mesic family of Ustic Calciargids. The meaning of each of these terms is defined later, but in a general way the name tells us the following.

Fine-loamy means that from a depth of 25–100 cm there is no marked contrast in particle-size class, the content of clay is between 18% and 35%, 15% or more of the material is coarser than 0.1 mm in diameter (fine sand to very coarse sand plus gravel), but less than 35% by volume of the material is rock fragments 2.0 mm or more in diameter (less than about 50% by weight). The average texture, then, is more likely to be loam, clay loam, or sandy clay loam. *Mixed* means a mixed mineralogy that is less than 40% of any one mineral other than quartz in the fraction between 0.02 and 2.0 mm in diameter; less than 20% (by weight) glauconitic pellets in the fine earth fraction; a total iron plus gibbsite (by weight) in the fine earth fraction of 5% or less; a fine earth fraction that has at least one of the following: free carbonates, the pH of a suspension of 1 g soil in 50 mL 1 M NaF of 8.4 or less after 2 min, or a ratio of −1500 kPa water to measured clay of 0.6 or less. *Superactive* means the CEC divided by the clay content (%) is 0.60 or more, which indicates the soil is relatively high in bases. *Mesic* indicates a mesic temperature regime, that is, the mean annual soil temperature is between 8°C and 15°C (47°F and 59°F) and the soil temperature fluctuates more than 6°C between summer and winter. In other words, the soil is somewhere in the midlatitudes, summer is warm or hot, and winter is cool or cold. *Depth of soil* when no class is used, in Ustic Calciargids, means the soil is 50 cm or more deep.

It is not necessary to know the exact criteria in the *Keys to Soil Taxonomy* in order to communicate useful information about a soil. It is necessary to know the language of *Soil Taxonomy*. For example, from Ustic Calciargids one knows the following.

Ustic at the subgroup level of an Aridisol means that the soil is moister than what is typical for an Aridisol or aridic soil moisture regime and close to having an ustic moisture regime. *Calci* means the soil has a calcic horizon within 150 cm of the soil surface. *Argi* denotes presence of an argillic horizon. The *id* means it is an Aridisol. Therefore, one can say that the soil occurs in an arid, temperate climate. Presence of an argillic horizon implies that the soil occurs on stable, older landscape. It has a calcic horizon and under irrigation, Fe chlorosis may be a problem in sensitive plants. If the soil is not irrigated, it can be used only for limited grazing.

31.8 Forming Names

31.8.1 Names of Orders, Suborders, and Great Groups

The names of the orders, suborders, and great groups that are currently recognized are presented in Chapter 33 under each order.

31.8.1.1 Names of Subgroups

The name of a subgroup consists of the name of a great group modified by one or more adjectives. As explained earlier, the adjective typic is used for the subgroup that is thought to typify the central concept of the great group, or for soils that fail to meet the criteria of the other subgroups defined for a great group.

Intergrade subgroups that have, in addition to the properties of their great group, some properties of another taxon carry the name of the other taxon in the form of an adjective. The names of orders, suborders, or great groups or any of the prior (first) formative elements of those names may be used in the form of an adjective in subgroup names. A few soils may have aberrant properties of two great groups that belong in different orders or suborders. For these, it is necessary to use two names of taxa as adjectives in the subgroup name.

Extragrade subgroups carry the name of one or more special descriptive adjectives (Table 31.5) to modify the name of the great group and connote the nature of the aberrant properties.

31.8.1.2 Names of Intergrades Toward Other Great Groups in the Same Suborder

If the aberrant property of a soil is one that is characteristic of another great group in the same suborder, only the distinctive formative element of the great group name is used to indicate the aberrant properties. Thus, Typic Argidurid is defined, in part, as having an indurated or very strongly cemented duripan. If the only aberrant feature of an Argidic Argidurid is that the duripan is strongly cemented or less cemented throughout, it is considered to intergrade toward the Argids. The name, however, is Argidic Argidurids, not Haplargidic Argidurids. Only the prior (first) formative element is used in adjectival form if the two great groups are in the same suborder.

31.8.1.3 Names of Intergrades Toward a Great Group in the Same Order but Different Suborder

Two kinds of names have been chosen here. If the only aberrant features are color and moisture regime and the hue is too yellow or the chroma is too high or too low for the typic subgroup, the adjectives aeric or aquic are used.

If an Epiaquult has chroma too high for the typic subgroup, but has no other aberrant feature, it is placed in an aeric subgroup. Using an adjective taken from the suborder, udic, would not suggest that the difference is one of aeration alone.

If the only aberrant feature of a Hapludult is redoximorphic features that are too shallow for a Typic Hapludult, the adjective aquic is used in the subgroup name. If redox depletions (accompanied by aquic conditions, unless artificially drained) appear within the upper 60 cm of the argillic horizon, the soil is called an Aquic Hapludult, not an Aquultic Hapludult.

In other instances, the adjective in the subgroup name is made from the first two formative elements of the appropriate great group name in that suborder. For example, if a Paleudult has both shallow redoximorphic features and some plinthite, it is called a Plinthaquic Paleudult, not a Plinthaquultic Paleudult.

Note that the formative element for the order is not repeated in the adjective if the two great groups are in the same order.

31.8.1.4 Names of Subgroups not Intergrading Toward Any Known Kind of Soil (Extragrade)

Some soils have aberrant properties that are not characteristic of a class in a higher category of any order, suborder, or great group. One example might be taken from the concave pedons that are at the base of slopes, in depressions, or in other places where new soil material accumulates slowly on the surface. In these soils, material is added to the A horizon. The presence of an overthickened A horizon is not used to define any great group, but the soils lie outside the range of the typic subgroup and there is no class toward which they intergrade. Hence, a descriptive adjective is required. For this particular situation, the adjective cumulic (L. *cumulus*, heap, plus ic, Gr. *ikos*) is used to form the subgroup names. Pachic is used to indicate an overthickened epipedon if there is no evidence of new material at the surface.

Other soils lie outside the range of typic subgroups in an opposite direction. Such soils are, in effect, truncated by hard rock and are shallow or are intermittent between rock outcrops. They are, in effect, intergrades to nonsoil and are called lithic subgroups. The names of formative elements in groups of this sort, which are called extragrades, are listed together with their derivation in Table 31.5.

31.8.2 Names of Families

Each family requires one or more names. The technical family name consists of a series of descriptive terms modifying the subgroup name. For these terms the class names that are given later for particle-size class, mineralogy, and so on, in family differentiae are used. To have consistent nomenclature, the order of descriptive terms in names of families is particle-size class, mineralogy class, cation exchange activity class, calcareous and reaction class, soil temperature class, soil depth class, rupture resistance class, classes of coatings, and classes of cracks.

Redundancy in names of families is avoided. Particle-size class and temperature classes should not be used in the family name if they are specified above the family. Psamments, by definition, all have a sand or loamy sand texture and are in a sandy particle-size class, unless they are ashy. It is, therefore, redundant to use a particle-size class for Psamments, unless they are ashy.

Information Centre*

32.1 Introduction

Soil classification is probably as old as farming. The fact that, around 8000 BP, the first farming communities in Europe settled on the better loess soils indicates that, during these times, farmers were already capable of distinguishing between the more and less productive soils. The oldest historical record of soil classification is most likely the Chinese book, *Yugong*, in which the soils of China were classified into three categories and nine classes, based on soil color, texture, and hydrological features (Gong, 1994). Even today, such criteria are still in use by farmers to differentiate soils. Studies on indigenous soil knowledge in northern Ghana, for example, have shown that farmers use texture, color, stoniness, and soil depth to stratify the soils (Asiamah et al., 1997).

This chapter will describe (1) the *Legend of the Soil Map of the World* (FAO–UNESCO, 1974), its revised version (FAO–UNESCO, 1988), and the *World Reference Base for Soil Resources* (WRB) (ISSS–ISRIC–FAO, 1994, 1998; IUSS Working Group WRB, 2006) as international systems of soil classification and correlation; (2) the French system of soil classification (CPCS, 1967), which is still the system in use in large parts of West and Central Africa and the new *Référentiel Pédologique Français* (AFES–INRA, 1990, 1992); (3) the systems of soil classification used in Russia (VASKhNIL, 1986; Shishov et al., 2004); (4) the recently developed soil classification system of China (Gong and Zhang, 2007); and (5) the newly developed system of soil classification for Australia (Isbell, 1996) as classification systems, which are covering a range of ecological regions (from the arctic to the [sub]tropics). In addition, some attention will be paid to the soil classification systems in use in Brazil, Canada, England and Wales, Germany, New Zealand, and South Africa, which are more oriented toward one ecological region.

32.2 The FAO–UNESCO Legend of the Soil Map of the World 1:5,000,000

32.2.1 Introduction

The *Soil Map of the World* is a response to recommendations made by the international soil community in the 1950s to give special attention to developing the classification and correlation of the soils of great regions of the world (FAO–UNESCO, 1974). It was the first attempt to prepare, on the basis of international cooperation, a soil map covering all continents of the world using a uniform legend, thus enabling the correlation of soil units and the comparison of soils on a global scale. It should be borne in mind that the *Soil Map of the World* project produced a legend accompanying the map and not a global soil classification system.

32.2.2 History

The Food and Agriculture Organization (FAO) and United Nations Educational, Scientific, and Cultural Organization (UNESCO), in association with the International Society of Soil Science (ISSS), jointly took up the recommendations made during the Sixth and Seventh ISSS Congresses in 1956 and 1960 to prepare a *Soil Map of the World* at scale 1:5,000,000. The project started in 1961 and was based on the compilation of available soil survey material and field correlation. A scientific advisory panel was convened to study the scientific and methodological problems relative to the preparation of such a soil map of the world.

During a number of meetings, the advisory panel worked out the organization of the field correlation, selected the scale of the map and its topographic base, and prepared the first draft definitions of soil units. These were presented to the Eighth ISSS Congress in 1964. In 1966, a general agreement was reached on the principles for constructing the international legend, on the preparation of the definitions of soil units, and on the adoption of a unified nomenclature. The first draft was presented in 1968 to the Ninth ISSS Congress, which approved the outline of the legend, the definitions, and the nomenclature. Moreover, it recommended that the *Soil Map of the World* be published as soon as possible.

32.2.3 Objectives

The objectives of the *Soil Map of the World* project (FAO–UNESCO, 1974) were to (1) make a first appraisal of the world's soil resources, (2) supply a scientific basis for the transfer of experience between areas with similar environments, (3) promote the establishment of a generally accepted soil classification and nomenclature, (4) establish a common framework for more detailed investigations in developing areas, (5) serve as a basic document for educational, research, and development activities, and (6) strengthen international contacts in the field of soil science.

32.2.4 The Soil Units

The soil units that form the basis of the *FAO–UNESCO Legend* have been defined in terms of measurable and observable properties of the soil itself. They form a monocategorical and not a taxonomic system with different levels of generalization. However, for the sake of logical presentation, they can be grouped on generally accepted principles of soil formation (FAO–UNESCO, 1974). Based on soil development status, material, and major geographical zone, 24 major soils and 106 soil units are distinguished (Table 32.1).

The soil units are characterized by the presence or absence of diagnostic horizons and properties. Key properties have been selected on the basis of generally accepted principles of soil formation so as to correlate with as many other characteristics as possible. Clusters of properties have been combined into so-called diagnostic horizons, which have been adopted to formulate the definitions of the soil units. The definitions and nomenclature of the diagnostic horizons and properties used are drawn from those adopted in *Soil Taxonomy* (Soil Survey Staff, 1975), but the definitions have been summarized and sometimes simplified to serve the purpose of the legend. For full background and details, the user is referred to *Soil Taxonomy* (Soil Survey Staff, 1975, 1996). A brief overview of the diagnostic horizons and properties used in the *FAO–UNESCO Legend* and their meaning are given in Table 32.2.

Volume I of the *Legend of the Soil Map of the World* provides a key to the soil units, which can be used to identify the soil (FAO–UNESCO, 1974). An abbreviated version listing the major soil units is reproduced in Table 32.3.

32.3 The Revised Legend of the FAO–UNESCO Soil Map of the World

32.3.1 Introduction

In 1988, a revised version of the *Legend of the Soil Map of the World* was issued (FAO–UNESCO, 1988), which assessed to what extent the objectives of the original *Legend of the Soil Map of the World* (FAO–UNESCO, 1974; Section 32.2.3) were met and analyzed its present day function. It was realized that, in order to keep the maps and accompanying legend up to date, revisions were necessary. New knowledge on soils, particularly from the developing world, had emerged and more recent soil surveys had yielded better insight into the distribution of soils in the world. The *Revised Legend* did not replace the *1974 Legend*, which is still the reference for the *Soil Map of the World*. The *Revised Legend* served also as a framework for the establishment by the ISSS of the WRB (Section 32.4).

32.3.2 Amendments to the 1974 Legend of the Soil Map of the World

The monocategorical character of the *1974 Legend*, using only soil units, was transformed into a multicategorical system with major soil groupings (MSGs; e.g., Fluvisols), soil units

TABLE 32.2 Diagnostic Horizons and Properties in the *FAO–UNESCO Legend of the Soil Map of the World 1:5,000,000*

Horizons

Albic E	Light colored eluvial horizon generally associated with argic and spodic horizons
Argillic B	Subsurface horizon with distinct clay accumulation
Calcic	Horizon with accumulation of calcium carbonate
Cambic B	Subsurface horizon showing evidence of alteration relative to the underlying horizon(s)
Gypsic	Horizon with accumulation of gypsum
Histic H	Poorly aerated, waterlogged, highly organic surface horizon
Mollic A	Thick, dark-colored surface horizon with high base saturation and moderate to high organic matter content
Natric B	Subsurface horizon with distinct clay accumulation and a high exchangeable sodium percentage
Ochric A	Weakly developed surface horizon, either light colored, or thin, or having a low organic matter content
Oxic B	Strongly weathered subsurface horizon with low cation exchange capacity (CEC)
Spodic B	Dark-colored subsurface horizon with illuvial aluminoorganic complexes, with or without iron
Sulfuric	Extremely acid subsurface horizon with sulfuric acid resulting from oxidation of sulfides
Umbric A	Thick, dark-colored surface horizon with low base saturation and moderate to high organic matter content

Properties and materials

Abrupt textural change	Sharp increase in clay content within a limited depth range
Albic material	Light colored mineral soil material
Aridic moisture regime	No available water in any part of the moisture control section for as long as 90 consecutive days or more than half the time when soil temperature (at 50 cm depth) is above 5°C
Exchange complex dominated by amorphous material	CEC (pH 8.2) more than 150 $cmol_c \cdot kg^{-1}$ clay; if 15 bar water content is 20% or more, pH of NaF is more than 9.4; ratio of 15 bar water content to clay is more than 1.0; more than 0.6% organic carbon; DTA shows low-temperature endotherm; bulk density is 0.85 $g\ cm^{-3}$ at 1/3 bar tension, low CEC (<24 $cmol_c\ kg^{-1}$ clay by NH_4Cl)
Ferralic ferric	Iron concentrated in large mottles or concretions, or low CEC (<24 $cmol_c\ kg^{-1}$ clay by NH_4Cl)
Gilgai microrelief	Succession of enclosed microbasins and microknolls in level areas or microvalleys and microridges on slopes
High organic matter content	Organic matter content of 1.35% or more averaged to a depth of 100 cm or 1.5% organic matter in the upper part of the B horizon (acrisols only)
High salinity	EC of saturation extract more than 15 dS m^{-1} at 25°C at specified depths or more than 4 dS m^{-1} within 25 cm of the surface if pH (H_2O, 1:1) exceeds 8.5
Hydromorphic properties	Saturation with groundwater; occurrence of a histic H horizon; dominant neutral (N) hues or hues bluer than 10Y; saturation with water at some period of the year (unless artificially drained) with evidence of reduction or of reduction and segregation
Interfingering	Penetrations of an albic E horizon into an underlying argillic or natric B horizon, not wide enough to constitute tonguing
Permafrost	Perennial temperature at or below 0°C
Plinthite	Iron-rich, humus-poor soil material, which hardens irreversibly upon repeated wetting and drying
Slickensides	Polished and grooved ped surfaces that are produced by sliding past another
Smeary consistence	Presence of thixotropic soil material
Soft powdery lime	Accumulation of translocated calcium carbonate in soft powdery form
Sulfidic materials	Waterlogged deposit containing 0.75% or more sulfur and less than three times as much carbonates ($CaCO_3$ equivalent) as sulfur
Takyric features	Combination of heavy texture, polygonal cracks, and platy or massive surface crust
Thin iron pan	Black to dark reddish layer cemented by iron, by iron and manganese, or by iron–organic matter complexes
Tonguing	Penetrations of an albic E horizon into an argillic B horizon with specified dimensions
Vertic properties	Cracks 1 cm or more wide within 50 cm of the upper boundary of the B horizon, extending to the surface or at least to the upper part of the B horizon
Weatherable minerals	Presence of minerals considered to be unstable relative to other minerals such as quartz and 1:1 lattice clays and which produce plant nutrients upon weathering

Source: FAO–UNESCO. 1974. Soil map of the world 1:5,000,000. Volume I, Legend. United Nations Educational, Scientific and Cultural Organization, Paris, France.

(e.g., Dystric Fluvisols), and soil subunits (e.g., Gleyi-dystric Fluvisols). The introduction of a multicategorical system was necessitated by the increasing use of the *1974 Legend* in more detailed surveys, particularly in Africa, where during the 1980s 1:1,000,000 soil maps were produced of, for example, Kenya, Botswana, and Zambia.

The *Revised Legend of the Soil Map of the World* distinguishes 28 MSGs, 4 more than the *1974 Legend*, and 153 soil units, 47 more than in 1974. Major changes are (1) amalgamation of the Lithosols, Rendzinas, and Rankers into one MSG (Leptosols), since the three had been difficult to show on the map; (2) deletion of the Xerosols and Yermosols, which were characterized by an

TABLE 32.3 Key to Major Soil Units of the 1974 *FAO–UNESCO Legend*

Soils having an H horizon of 40 cm or more (60 cm or more if the organic material consists mainly of sphagnum or moss or has a bulk density of less than 0.1 g cm⁻³) either extending down from the surface or taken cumulatively within the upper 80 cm of the soil; the thickness of the H horizon maybe less when it rests on rock or on fragmental material of which the interstices are filled with organic matter

<div align="right">

Histosols (O)

</div>

Other soils that are limited in depth by continuous coherent and hard rock within 10 cm of the surface

<div align="right">

Lithosols (I)

</div>

Other soils that, after the upper 20 cm have been mixed, have 30% or more clay in all horizons to at least 50 cm from the surface; at some period in most years have cracks at least 1 cm wide at a depth of 50 cm, unless irrigated, and have one or more of the following characteristics: gilgai microrelief, intersecting slickensides, or wedge-shaped or parallelepiped structural aggregates at some depth between 25 and 100 cm from the surface

<div align="right">

Vertisols (V)

</div>

Other soils developed from recent alluvial deposits, having no diagnostic horizons other than (unless buried by 50 cm or more new material) an ochric or an umbric A horizon, a histic H horizon, or a sulfuric horizon

<div align="right">

Fluvisols (J)

</div>

Other soils having high salinity and having no diagnostic horizons (unless buried by 50 cm or more new material) an A horizon, an H horizon, a cambic B horizon, a calcic or a gypsic horizon

<div align="right">

Solonchaks (Z)

</div>

Other soils showing hydromorphic properties within 50 cm of the surface; having no diagnostic horizons other than (unless buried by 50 cm or more new material) an A horizon, an H horizon, a cambic B horizon, a calcic or gypsic horizon

<div align="right">

Gleysols (G)

</div>

Other soils having either a mollic or an umbric A horizon possibly overlying a cambic B horizon or an ochric A horizon and a cambic B horizon; having no other diagnostic horizons (unless buried by 50 cm or more new material); having to a depth of 35 cm or more one or both of (a) a bulk density (at 1/3 bar water retention) of the fine earth (less than 2 mm) fraction of the soil of less than 0.85 g cm⁻³ and an exchange complex dominated by amorphous material; (b) 60% or more vitric volcanic ash, cinders, or other vitric pyroclastic material in the silt, sand, and gravel fractions

<div align="right">

Andosols (T)

</div>

Other soils of coarse texture consisting of albic material occurring over a depth of at least 50 cm from the surface or showing characteristics of argillic, cambic, or oxic B horizons which, however, do not qualify as diagnostic horizons because of textural requirements; having no diagnostic horizons other than (unless buried by 50 cm or more new material) an ochric A horizon

<div align="right">

Arenosols (Q)

</div>

Other soils having no diagnostic horizons or none other than (unless buried by 50 cm or more new material) an ochric A horizon

<div align="right">

Regosols (R)

</div>

Other soils having an umbric A horizon, which is not more than 25 cm thick; having no other diagnostic horizons (unless buried by 50 cm or more new material)

TABLE 32.3 (continued)   Key to Major Soil Units of the 1974
FAO–UNESCO Legend

Other soils having an argillic B horizon with a clay distribution, where the
  percentage of clay does not decrease from its maximum amount by as much
  as 20% within 150 cm of the surface; lacking plinthite within 125 cm of the
  surface; lacking vertic and ferric properties

Nitosols (N)

Other soils having an argillic B horizon; having a base saturation, which is
  less than 50% (by NH_4OAc) in at least some part of the B horizon within
  125 cm of the surface

Acrisols (A)

Other soils having an argillic B horizon

Luvisols (L)

Other soils having a cambic B horizon or an umbric A horizon, which is
  more than 25 cm thick

Cambisols (B)

I, Legend. United Nations Educational, Scientific and Cultural Organization,
Paris, France.

aridic moisture regime (as a general principle, climatic criteria
were not to be used in separating the soil units); (3) division of
the Acrisols and Luvisols, in 1974 distinguished by base satura-
tion, into four MSGs, introducing clay activity as an additional
separating criterion; (4) introduction of new MSGs (Alisols,
Calcisols, Gypsisols, Lixisols, Plinthosols, and Anthrosols); and
(5) renaming of Nitosols (Nitisols). A listing of the MSGs and the
soil units is given in Table 32.4.

The diagnostic horizons and properties have also been
largely adapted. In 1974, they were fairly similar to those in
Soil Taxonomy (Soil Survey Staff, 1975), but in 1988, many were
redefined and renamed and new additions made. The argillic
and oxic B horizons were renamed argic and ferralic B horizons,
respectively. The argic B horizon now includes both the argillic
and the kandic horizon as defined in *Soil Taxonomy* (Soil Survey
Staff, 1996), while the ferralic B horizon includes additional cri-
teria such as silt/clay ratio and water-dispersible clay content. An
addition is the thick, manmade, fimic A horizon, which includes
both the anthropic and plaggen epipedons of *Soil Taxonomy*.

Newly defined diagnostic properties include continuous hard
rock, fluvic, geric, nitic, and sodic properties. The 1974 hydro-
morphic properties were split into gleyic (wetness conditioned
by groundwater) and stagnic (wetness conditioned by surface
water) properties. Definitions of albic material, aridic moisture
regime, high organic matter content, and thin iron pan were
deleted as they are no longer used in defining soil units. Andic
properties have replaced the 1974 exchange complex dominated
by amorphous material.

A brief overview of the diagnostic horizons and proper-
ties used in the *Revised Legend* and their meaning is given in
Table 32.5. A key to the MSGs in the *Revised Legend* is given
in Table 32.6.

32.4 The World Reference Base for Soil Resources

32.4.1 Introduction

The first official version of the *World Reference Base for Soil
Resources* (WRB) was released at the 16th World Congress of
Soil Science at Montpellier in 1998. At the same event, it was
also endorsed and adopted as the system for soil correlation and
international communication of the International Union of Soil
Sciences (IUSS). It is also serving as a correlation scheme for soil
maps and databases for the European Union. Although it was not
designed for, in several countries it is also applied for different
scale of soil mapping. The current official version was released
at the 18th World Congress of Soil Science in Philadelphia in
2006, and an updated digital version was published in 2007 on
the official, FAO-hosted Web site of the WRB. The main text was
translated into 14 languages (Arabic, Chinese, French, German,
Hungarian, Italian, Japanese, Latvian, Lithuanian, Polish,
Rumanian, Russian, Spanish, and Vietnamese) and most trans-
lations are also available online on the Web site http://www.fao.
org/nr/land/soils/soil/wrb-documents/jp/

32.4.2 History

The WRB was initiated by the ISSS, FAO, and ISRIC to "provide
scientific depth and background to the 1988 FAO–UNESCO–
ISRIC *Revised Legend of the Soil Map of the World*, so that it incor-
porates the latest knowledge relating to global soil resources and
interrelationships" (ISSS–ISRIC–FAO, 1994). The initiative was
closely related to the *Soil Map of the World 1:5,000,000* project
of FAO and UNESCO. After its completion in the early 1980s,
it was realized that 20 years had elapsed since the project had
started. During this period, numerous new soil surveys, often
using local or national soil classification systems, had been car-
ried out both in developing and developed countries, generating
new knowledge and insight on the distribution and potential of
our soil resources. If the *Soil Map of the World* were to retain its
value as a global soil resource inventory, it needed regular updat-
ing with the most recent information.

Preliminary discussions were started on the establishment
of an International Reference Base for Soil Classification (IRB),
an initiative undertaken by FAO and UNESCO, supported by
the United Nations Environmental Program (UNEP) and the
ISSS. The intention of the IRB project was to work toward the
establishment of a framework through which existing soil clas-
sification systems could be correlated and ongoing soil classi-
fication work could be harmonized (Dudal, 1990). Meetings
were organized in Sofia, Bulgaria, to commence such an interna-
tional program. The outcomes were draft definitions of 16 MSGs
occurring globally.

During the ISSS congresses in 1982 and 1986 and expert con-
sultations in 1987 and 1988, the IRB took form, and as a result,
20 MSGs were identified and agreed upon as being representa-
tive of the principal components of the world's soil cover.

Source: FAO–UNESCO. 1988. FAO–UNESCO soil map of the world, revised legend. World Soil Resources Report No. 60. Food and Agriculture Organization, Rome, Italy.

Subsequently, it became clear that some of the proposed 20 MSGs were too broad to be defined consistently and, consequently, had to be subdivided. By doing so, the list of MSGs became very close to those of the *Revised Legend of the Soil Map of the World* (FAO–UNESCO, 1988). As a result, it was decided in 1992 to adopt the revised legend as the frame for further IRB work. This was also prompted by the fact that both the *Revised Legend* and the IRB were supported by the ISSS and that it would be inappropriate to pursue two programs, which essentially had the same goal, namely, to arrive at a rational inventory of global soil resources (ISSS–ISRIC–FAO, 1994, FAO–ISRIC–ISSS, 1998). The two programs were, therefore, merged under the name WRB. After 8 years of data collection and intensive worldwide testing of the first edition (1998), the second edition (2006 and 2007) was presented after broad discussions. The text of the chapters to follow will be based mostly on the current version (IUSS Working Group WRB, 2006) indicating significant changes from the earlier edition.

32.4.3 Objectives

The specific objectives of the WRB are to (1) develop an internationally acceptable framework for delineating soil resources to which national classifications can be attached and related, using the *FAO Revised Legend* as a guideline; (2) provide this framework with a sound scientific base, so that it can also serve different applications in related fields, such as agriculture, geology, hydrology, and ecology; (3) acknowledge in the framework important lateral aspects of soils and soil horizon distribution as characterized by topo- and chronosequences; and (4) emphasize the morphological characterization of soils rather than to follow a purely analytical approach.

32.4.4 Concepts and Principles

The general principles on which the WRB is based were laid down during the early Sofia meetings in 1980 and 1981 and further elaborated upon by the working groups entrusted with its development. These general principles can be summarized as follows: (1) The classification of soils is based on soil properties defined in terms of diagnostic horizons, properties, and materials, which to the greatest extent possible should be measurable and observable in the field; (2) selection of diagnostic horizons, properties, and materials takes into account their relationship with soil-forming processes; however, at a high level of generalization, it also attempts to select, to the extent possible, diagnostic features, which are of significance for management purposes; (3) climatic parameters are not applied in the classification of soils. It is fully realized that they should be used for interpretation purposes, in dynamic combination with soil properties, but they should not form part of soil definitions; (4) the WRB is a comprehensive classification system that enables people to accommodate their national classification system. It comprises two tiers of categorical detail: *the reference base*, limited to the first level only and having 32 reference soil groups (RSGs) and the *WRB classification system*, consisting of combinations of a set of prefix and suffix qualifiers that are uniquely defined and added to the name of the RSG, allowing very precise characterization and classification of individual soil profiles. The first edition of the *WRB*, published in 1998, comprised 30 RSGs; the second edition, published in 2006, has 32 RSGs. Definitions and descriptions of lower level soil units reflect variations in soil characteristics both vertically and laterally so as to account for spatial linkages within the landscape. The term "Reference Base" is connotative

TABLE 32.5 Diagnostic Horizons and Properties, 1988 *Revised Legend of the Soil Map of the World*

Horizons

Albic E	Light colored eluvial horizon generally associated with argic and spodic horizons
Argic B	Subsurface horizon with distinct clay accumulation
Calcic	Horizon with accumulation of calcium carbonate
Cambic B	Subsurface horizon showing evidence of alteration relative to the underlying horizon(s)
Ferralic B	Strongly weathered subsurface horizon with low CEC
Fimic A	Surface and subsurface horizons resulting from long-continued cultivation
Gypsic	Horizon with accumulation of gypsum
Histic H	Poorly aerated, waterlogged, highly organic surface horizon
Mollic A	Thick, dark-colored surface horizon with high base saturation and moderate to high organic matter content
Natric B	Subsurface horizon with distinct clay accumulation and a high exchangeable sodium percentage
Ochric A	Weakly developed surface horizon, either light colored, or thin, or having a low organic matter content
Petrocalcic	Continuous cemented or indurated calcic horizon
Petrogypsic	Continuous cemented or indurated gypsic horizon
Spodic B	Dark-colored subsurface horizon with illuvial aluminoorganic complexes, with or without iron
Sulfuric	Extremely acid subsurface horizon with sulfuric acid resulting from oxidation of sulfides
Umbric A	Thick, dark-colored surface horizon with low base saturation and moderate to high organic matter content

Properties

Abrupt textural change	Sharp increase in clay content within a limited depth range
Andic	High acid oxalate extractable Al and Fe content, low bulk density, high phosphate retention, high amount of coarse volcanoclastic material
Calcareous	Strong effervescence with 10% HCl (more than 2% calcium carbonate)
Calcaric	Presence of calcareous soil material between 20 and 50 cm depth
Continuous hard rock	Presence of coherent rock, practically impermeable for roots
Ferralic	Low CEC ($<24\,cmol_c\,kg^{-1}$ clay or $4\,cmol_c\,kg^{-1}$ fine earth)
Ferric	Presence of many coarse mottles or large iron concretions
Fluvic	Presence of fresh fluviatile, lacustrine, or marine sediments at the surface
Geric	Extremely low to negative effective CEC
Gleyic	Wetness producing reduced conditions caused by groundwater
Gypsiferous	Presence ≥5% gypsum
Interfingering	Narrow penetrations of an albic E horizon into an argic or natric B horizon
Nitic	Presence of strongly developed, nut-shaped structure and shiny pedfaces
Organic material	Material containing a very high amount of organic debris
Permafrost	Perennial temperature at or below 0°C
Plinthite	Presence of iron-rich, humus-poor material, which hardens irreversibly upon repeated wetting and drying
Salic	High soluble salt content (electrical conductivity $>15\,dS\,m^{-1}$ or >4 if pH exceeds 8.5)
Slickensides	Presence of polished and grooved surfaces produced by one mass sliding past another
Smeary consistence	Presence of thixotropic soil material
Sodic	ESP ≥ 15% or exchangeable Na + Mg percentage ≥50%
Soft powdery lime	Accumulation of translocated calcium carbonate in soft powdery form
Stagnic	Wetness producing reduced conditions caused by stagnating surface water
Strongly humic	High organic matter content
Sulfidic material	Waterlogged deposit containing sulfides and only moderate amounts of calcium carbonate
Tonguing	Wide penetrations of an albic E horizon into an argic B horizon or penetrations of a mollic A horizon into an underlying cambic B horizon or into a C horizon (Chernozems only)
Vertic	Presence of cracks, slickensides, wedge-shaped, or parallelepiped structural aggregates
Weatherable minerals	Presence of minerals unstable in a humid climate relative to other minerals

Source: FAO–UNESCO. 1988. FAO–UNESCO soil map of the world, revised legend. World Soil Resources Report No. 60. Food and Agriculture Organization, Rome, Italy.

TABLE 32.6 Key to MSGs of the 1988 *Revised Legend of the Soil Map of the World*

Soils having an H horizon, or an O horizon, of 40 cm or more (60 cm or more if the organic material consists mainly of sphagnum or moss or has a bulk density of less than 0.1 Mg m^{-3}) either extending down from the surface or taken cumulatively within the upper 80 cm of the soil; the thickness of the H or O horizon may be less when it rests on rocks or on fragmental material of which the interstices are filled with organic matter

Histosols (HS)

Other soils that are coarser than sandy loam to a depth of at least 100 cm from the surface, having <35% of rock fragments or other coarse fragments in all subhorizons within 100 cm of the surface, having no diagnostic horizons other than an ochric A horizon or an albic E horizon

Arenosols (AR)

Other soils in which human activities have resulted in a profound modification or burial of the original soil horizons, through removal or disturbance of surface horizons, cuts and fills, secular additions of organic materials, long-continued irrigation, etc.

Anthrosols (AT)

Other soils having no diagnostic horizons other than an ochric or umbric A horizon; lacking soft powdery lime

Regosols (RG)

Other soils that are limited in depth by continuous hard rock or highly calcareous materials (calcium carbonate equivalent >40%) or a continuous cemented layer within 30 cm of the surface or having <20% of fine earth over a depth of 75 cm from the surface. Diagnostic horizons may be present

Leptosols (LP)

Other soils having a spodic B horizon

Podzols (PZ)

Other soils having, after the upper 18 cm have been mixed. Thirty percent or more clay in all horizons to a depth of 50 cm; developing cracks from the soil surface downward which at some period in most years (unless the soil is irrigated) are at least 1 cm wide to a depth of 50 cm; having one or more of the following: Intersecting slickensides or wedge-shaped or parallelepiped structural aggregates at some depth between 25 and 100 cm from the surface

Vertisols (VR)

Other soils having ≥25% plinthite by volume in a horizon, which is at least 15 cm thick within 50 cm of the surface or within a depth of 125 cm when underlying an albic E horizon or a horizon that shows stagnic properties within 50 cm of the surface or gleyic properties within 100 cm of the surface

Plinthosols (PT)

Other soils showing fluvic properties and having no diagnostic horizons other than an ochric, mollic, an umbric A horizon, or a histic H horizon, or a sulfuric horizon, or sulfidic material within 125 cm of the surface

Fluvisols (FL)

Other soils having a ferralic B horizon

Ferralsols (FR)

Other soils showing salic properties and having no diagnostic horizons other than an ochric, umbric, or mollic A horizon, a histic H horizon, a cambic B horizon, a calcic, or a gypsic horizon

Solonchaks (SC)

TABLE 32.6 (continued) Key to MSGs of the 1988 *Revised Legend of the Soil Map of the World*

Other soils having an E horizon showing stagnic properties at least in part of the horizon and abruptly overlying a slowly permeable horizon within 125 cm of the surface and lacking a natric or a spodic B horizon

Planosols (PL)

Other soils, exclusive of coarse textured materials (except when a histic H horizon is present), showing gleyic properties within 50 cm of the surface; having no diagnostic horizons other than an A horizon, a histic H horizon, a cambic B horizon, a sulfuric horizon, a calcic, or a gypsic horizon; lacking plinthite within 125 cm of the surface

Gleysols (GL)

Other soils having a natric B horizon

Solonetz (SN)

Other soils showing andic properties to a depth of 35 cm or more from the surface and having a mollic or an umbric A horizon possibly overlying a cambic B horizon or an ochric A horizon and a cambic B horizon; having no other diagnostic horizons

Andosols (AN)

Other soils having a mollic A horizon with a moist chroma of 2 or less to a depth of at least 15 cm, showing uncoated silt and sand grains on structural pedfaces; having an argic B horizon

Greyzems (GR)

Other soils having an argic B horizon showing an irregular or broken upper boundary resulting from deep tonguing of the A into the B horizon or from the formation of discrete nodules larger than 2 cm, the exteriors of which are enriched and weakly cemented or indurated and have redder hues and stronger chromas than the interiors

Podzoluvisols (PD)

Other soils having a mollic A horizon with a moist chroma of 2 or less to a depth of at least 15 cm; having a calcic or petrocalcic horizon, or concentrations of soft powdery lime within 125 cm of the surface, or both

Chernozems (CH)

Other soils having a gypsic or petrogypsic horizon within 125 cm of the surface; having no diagnostic horizons other than an ochric A horizon, a cambic B horizon or an argic B horizon permeated with gypsum or calcium carbonate, a calcic or petrocalcic horizon

Gypsisols (GY)

Other soils having a mollic A horizon with a moist chroma of more than 2 to a depth of at least 15 cm; having one or more of the following: a calcic, petrocalcic, or gypsic horizon or concentrations of soft powdery lime within 125 cm of the surface

Kastanozems (KS)

Other soils having a calcic or a petrocalcic horizon, or a concentration of soft powdery lime, within 125 cm of the surface; having no diagnostic horizons other than an ochric A horizon, a cambic B horizon, or an argic B horizon, which is calcareous

Calcisols (CL)

Other soils having a mollic A horizon; having a base saturation (by NH$_4$OAc) of ≥50% throughout the upper 125 cm of the soil

Phaeozems (PH)

TABLE 32.6 (continued) Key to MSGs of the 1988 *Revised Legend of the Soil Map of the World*

Other soils having an argic B horizon with a clay distribution, which does not show a relative decrease from its maximum of more than 20% within 150 cm of the surface; showing gradual to diffuse horizon boundaries between the A and B horizons; having nitic properties in some subhorizon within 125 cm of the surface

Nitisols (NT)

Other soils having an argic B horizon, which has a CEC equal to or more than 24 cmol$_c$ kg^{-1} clay and a base saturation (by NH$_4$OAc) of less than 50% in at least some part of the B horizon within 125 cm of the surface

Alisols (AL)

Other soils having an argic B horizon, which has a CEC of less than 24 cmol$_c$ kg^{-1} clay and a base saturation (by NH$_4$OAc) of less than 50% in at least some part of the B horizon within 125 cm of the surface

Acrisols (AC)

Other soils having an argic B horizon, which has a CEC equal to or more than 24 cmol$_c$ kg^{-1} clay and a base saturation (by NH$_4$OAc) of 50% or more throughout the B horizon within 125 cm of the surface

Luvisols (LV)

Other soils having an argic B horizon, which has a CEC of less than 24 cmol$_c$ kg^{-1} clay and a base saturation (by NH$_4$OAc) of 50% or more throughout the B horizon within 125 cm of the surface

Lixisols (LX)

Other soils having a cambic B horizon

Cambisols (CM)

Source: FAO–UNESCO. 1988. FAO–UNESCO soil map of the world, revised legend. World Soil Resources Report No. 60. Food and Agriculture Organization, Rome, Italy.

of the common denominator function that the WRB assumes. Its units have sufficient width to stimulate harmonization and correlation of existing national systems; (5) the reference base is not meant to substitute for national soil classification systems but rather to serve as a common denominator for communication at an international level; (6) in addition to serving as a link between existing classification systems, the WRB also serves as a consistent communication tool for compiling global soil databases and for the inventory and monitoring of the world's soil resources. The nomenclature used to distinguish soil groups retains terms that have been used traditionally or that can be introduced easily in current language.

32.4.5 The Architecture of the WRB

Currently, the WRB comprises two tiers of categorical detail: (1) the RSGs and (2) the combination of RSGs with qualifiers, detailing the properties of the RSGs by adding a set of uniquely defined qualifiers. From the *FAO Revised Legend*, through the 1998 WRB edition, several changes occurred. In 1998, one MSG has been omitted (Greyzems), and three new ones are introduced (Cryosols, Durisols, and Umbrisols). Greyzems

were deleted as they constitute the smallest MSG and were amalgamated with the Phaeozems. Cryosols were newly introduced to identify a group of soils, which occur under the unique environmental conditions of thawing and freezing. Durisols have been added to group soils together, which have accumulation of secondary silica, analogous to the Calcisols and Gypsisols. Umbrisols constitute the group of soils that have a thick accumulation of desaturated organic matter at the surface and are the natural counterpart of Chernozems, Kastanozems, and Phaeozems.

The second edition of the *WRB* has undergone a major revision. Technosols and Stagnosols have been introduced, leading to 32 RSGs instead of 30. The Technosols are soils with a certain amount of artifacts, a constructed geomembrane or technic hard rock. The Stagnosols unify the former Epistagnic subunits of many other RSGs. Some rearrangement has taken place in the order of the key, with Anthrosols, Solonetz, Nitisols, and Arenosols moving upward. The definitions of many diagnostic soil horizons, soil properties, and materials have been adjusted. An overview of the diagnostic categories is presented in Table 32.7. The number of qualifiers almost doubled (currently 179), and a significant change was the subdivision of qualifiers into prefix and suffix ones. Prefix qualifiers comprise those that are typically associated with the RSG (in order of their importance) and the intergrades to other RSGs (in order of the key). All other qualifiers are listed as suffix qualifiers.

The RSGs are defined by the key. For each RSG number of possible prefix and suffix qualifiers are listed in priority order. After determining the RSG, the applying prefix qualifier names are put before the RSG name and applying suffix qualifier names are placed between brackets following the RSG name.

The current scheme of the WRB proved to be capable of indicating most of the soil's properties and performed properly for correlation purposes. However, recent applications for mapping purposes indicated that when generalization is required, important information may not show with the current set of the qualifiers. Although WRB was not primarily designed to serve mapping purposes, it is increasingly used for that. Therefore, an addendum has been developed to serve the need for small-scale mapping. The "Guidelines for constructing small-scale map legends using the World Reference Base for Soil Resources" (IUSS Working Group WRB, 2010) is available online at the WRB Web site.

32.4.6 The WRB Reference Soil Groups

The key to the RSGs in the WRB stems from the *Legend of the Soil Map of the World*. The history behind the key to the major soil units of the *Legend of the Soil Map of the World* reveals that it is mainly based on functionality; the key was conceived to derive the correct classification as efficiently as possible. The sequence of the major soil units was such that the central concept of the major soils would come out almost automatically by specifying

TABLE 32.7   An Overview of the Diagnostic Horizons, Properties, and Materials of the WRB

Surface horizons and subsurface diagnostic horizons at shallow depth

Anthraquic horizon	An anthraquic horizon (from Greek anthropos, human, and Latin aqua, water) is a human-induced surface horizon that comprises a puddled layer and a plow pan
Anthric horizon	A moderately thick, dark-colored surface horizon that is the result of long-term cultivation (plowing, liming, fertilization, etc.)
Folic horizon	Surface horizon or subsurface horizon at shallow depth, consisting of well-aerated organic soil material
Fulvic horizon	Thick, black surface horizon having a low bulk density and high organic carbon content conditioned by short-range-order minerals (usually allophane) and/or organoaluminum complexes
Histic horizon	A surface horizon or a subsurface horizon occurring at shallow depth that consists of poorly aerated organic material
Hortic horizon	A human-induced mineral surface horizon that results from deep cultivation, intensive fertilization, and/or long-continued application of human and animal wastes and other organic residues
Hydragric horizon	A human-induced subsurface horizon associated with wet cultivation
Irragric horizon	Human-induced mineral surface horizon that builds up gradually through continuous application of irrigation water with substantial amounts of sediments
Melanic horizon	Thick, black surface horizon conditioned by short-range-order minerals (usually allophane) and/or organoaluminum complexes
Mollic horizon	Well-structured, dark surface horizons with high base saturation and moderate to high organic carbon content
Plaggic horizon	An organic matter—rich, thick, black or brown human-induced low base mineral surface horizon that has been produced by long-continued manuring
Takyric horizon	Finely textured surface horizon consisting of a dense surface crust and a platy lower part; formed under arid conditions in periodically flooded soils
Terric horizon	A human-induced mineral surface horizon that develops through addition of earthy manures, compost, beach sands, or mud over a long period of time
Umbric horizon	Well-structured, dark surface horizon with low base saturation and moderate to high organic matter content
Yermic horizon	Surface horizon of rock fragments ("desert pavement") usually, but not always, embedded in a vesicular crust and covered by a thin eolian sand or loess layer
Voronic horizon	Deep, well-structured, blackish surface horizon with a high base saturation, high organic matter content, strong biological activity, and well-developed, usually granular, structure. Its carbon content is intermediate between a mollic horizon and a histic horizon

Subsurface diagnostic horizons

Albic horizon	Bleached eluviation horizon with the color of uncoated soil material, usually overlying an illuviation horizon
Argic horizon	Subsurface horizon having distinctly more clay than the overlying horizon as a result of illuvial accumulation of clay and/or pedogenetic formation of clay in the subsoil and/or destruction or selective erosion of clay in the surface soil
Cambic horizon	Genetically young subsurface horizon showing evidence of alteration relative to underlying horizons: modified color, removal of carbonates, or presence of soil structure
Cryic horizon	Perennially frozen horizon in mineral or organic soil materials
Calcic horizon	Horizon with distinct calcium carbonate enrichment
Duric horizon	Subsurface horizon with weakly cemented to indurated nodules cemented by silica (SiO_2) known as "durinodes"
Ferralic horizon	Strongly weathered horizon in which the clay fraction is dominated by low activity clays and the sand fraction by resistant materials such as iron-, aluminum-, manganese-, and titanium oxides
Ferric horizon	Subsurface horizon in which segregation of iron has taken place to the extent that large mottles or concretions have formed in a matrix that is largely depleted of iron
Fragic horizon	Dense, noncemented subsurface horizon that can only be penetrated by roots and water along natural cracks and streaks
Gypsic horizon	Horizon with distinct calcium sulfate enrichment
Natric horizon	Subsurface horizon with more clay than any overlying horizon(s) and high exchangeable sodium percentage; usually dense, with columnar or prismatic structure
Nitic horizon	Clay-rich subsurface horizon with a moderate to strong polyhedric or nutty structure with shiny pedfaces
Petrocalcic horizon	Continuous, cemented, or indurated calcic horizon
Petroduric horizon	Continuous subsurface horizon cemented mainly by secondary silica (SiO_2), also known as a "duripan"
Petrogypsic horizon	Cemented horizon containing secondary accumulations of gypsum ($CaSO_4 \cdot 2H_2O$)
Petroplinthic horizon	Continuous layer indurated by iron compounds and without more than traces of organic matter
Pisoplinthic horizon	A pisoplinthic horizon contains nodules that are strongly cemented or indurated with Fe (and in some cases also with Mn)

TABLE 32.7 (continued)   An Overview of the Diagnostic Horizons, Properties, and Materials of the WRB

Plinthic horizon	Subsurface horizon consisting of an iron-rich, humus-poor mixture of kaolinitic clay with quartz and other constituents and which changes irreversibly to a hardpan or to irregular aggregates on exposure to repeated wetting and drying with free access of oxygen
Salic horizon	Surface or shallow subsurface horizon containing 1% of readily soluble salts or more
Sombric horizon	A dark-colored subsurface horizon containing illuvial humus that is neither associated with Al nor dispersed by Na
Spodic horizon	Dark-colored subsurface horizon with illuvial amorphous substances composed of organic matter and aluminum, with or without iron
Thionic horizon	An extremely acid subsurface horizon in which sulfuric acid is formed through oxidation of sulfides
Vertic horizon	Subsurface horizon rich in expanding clays and having polished and grooved ped surfaces ("slickensides") or wedge-shaped structural aggregates formed upon repeated swelling and shrinking
Diagnostic properties	
Abrupt textural change	Very sharp increase in clay content within a limited vertical distance
Albeluvic tonguing	Iron-depleted material penetrating into an argic horizon along ped surfaces
Andic properties	Result from moderate weathering of mainly pyroclastic deposits. The presence of short-range-order minerals and/or organometallic complexes is characteristic for andic properties
Aridic properties	Refer to soil material low in organic matter, with evidence of eolian activity, light in color and (virtually) base-saturated
Continuous rock	Continuous rock is consolidated material underlying the soil, exclusive of cemented pedogenetic horizons such as petrocalcic, petroduric, petrogypsic, and petroplinthic horizons
Ferralic properties	Indicate that the (mineral) soil material has a "low" CEC or would have qualified for a ferralic horizon if it had been less coarsely textured
Geric properties	Mark soil material of very low-effective CEC or even acting as anion exchanger
Gleyic color pattern	Visible evidence of prolonged waterlogging and reducing conditions by shallow groundwater
Lithological discontinuity	Significant changes in particle-size distribution or mineralogy that represent differences in lithology within a soil
Reducing conditions	Lack of oxygen due the saturation of moisture in some parts of the soil
Secondary carbonates	Significant quantities of translocated lime, soft enough to be readily cut with a finger nail, precipitated from the soil solution rather than being inherited from the soil parent material
Stagnic color pattern	Visible evidence of prolonged waterlogging and reducing conditions by a perched water table
Vertic properties	Vertic properties are characterized with slickensides, or wedge-shaped aggregates, or cracks due to high clay content
Vitric properties	Apply to layers with volcanic glass and other primary minerals derived from volcanic ejecta, which contain a limited amount of short-range-order minerals or organometallic complexes
Diagnostic materials	
Artifacts	Artifacts solid or liquid substances that are created or substantially modified or brought to the surface by human activity from a depth, where they were not influenced by surface processes
Calcaric soil material	Soil material that contains more than 2% calcium carbonate equivalent and shows strong effervescence with 10% HCl in most of the fine earth
Colluvic material	Formed by sedimentation through human-induced erosion
Fluvic soil material	Refers to fluviatile, marine, and lacustrine sediments that receive fresh material at regular intervals or have received it in the recent past
Gypsiric soil material	Mineral soil material, which contains 5% or more gypsum (by volume)
Limnic material	Organic and mineral materials that are deposited in water by precipitation or through action of aquatic organisms, such as diatoms and other algae
Mineral material	The soil properties are dominated by mineral components
Organic soil material	Organic debris that accumulates at the surface and in which the mineral component does not significantly influence soil properties
Ornithogenic material	Material with strong influence of bird excrement
Sulfidic soil material	Waterlogged deposit containing sulfur, mostly sulfides, and not more than moderate amounts of calcium carbonate
Technic hard rock	Consolidated material resulting from an industrial process, with properties substantially different from those of natural materials
Tephric soil material	Unconsolidated, non or only slightly weathered products of volcanic eruptions, with or without admixtures of material from other sources

briefly a limited number of diagnostic horizons, properties, or materials. In the current WRB key, the RSGs are allocated to sets on the basis of dominant identifiers, that is, the soil-forming factors or processes that most clearly condition the soil formation. The sequencing of the groups is done according to the following principles:

1. First, organic soils key out to separate them from mineral soils (*Histosols*).
2. The second major distinction in the WRB is to recognize human activity as a soil-forming factor, hence the position of the *Anthrosols and Technosols* after the Histosols; it also appears logical to key out the newly introduced Technosols close to the beginning of the key, for the following reasons: One can almost immediately key out soils that should not be touched (toxic soils that should be handled by experts); a homogeneous group of soils in strange materials is obtained; politicians and decision-makers, who consult the key will immediately encounter these problematic soils.
3. Next are the soils with a severe limitation to rooting (*Cryosols and Leptosols*).
4. Then comes a group of RSGs that are or have been strongly influenced by water: *Vertisols, Fluvisols, Solonetz, Solonchaks,* and *Gleysols.*
5. The following set of soil groups are the RSGs in which iron (Fe) and/or aluminum (Al) chemistry plays a major role in their formation: *Andosols, Podzols, Plinthosols, Nitisols,* and *Ferralsols.*
6. Next comes the set of soils with perched water: *Planosols* and *Stagnosols.*
7. The next grouping comprises soils that occur predominantly in steppe regions and have humus-rich topsoils and a high base saturation: *Chernozems, Kastanozems,* and *Phaeozems.*
8. The next set comprises soils from the drier regions with accumulation of gypsum (*Gypsisols*), silica (*Durisols*), or calcium carbonate (*Calcisols*).
9. Then comes the soils with clay-rich subsoil: *Albeluvisols, Alisols, Acrisols, Luvisols,* and *Lixisols.*
10. Finally, relatively young soils or soils with very little or no profile development, or very homogenous sands, are grouped together: *Umbrisols, Arenosols, Cambisols,* and *Regosols.*

The key to the RSGs of the WRB is presented in Table 32.8. An example for the classification in the WRB system is presented in Figure 32.1.

The dark, cracking, clayey heavy soil satisfies the criteria of the mollic, the vertic, and the calcic horizons. Therefore, this soil will key out in the Vertisols reference group of the WRB. From the qualifiers, the ones indicated with bold in the figure apply. According to the rules of classification (IUSS Working Group WRB, 2007), the name of the soil is *Calcic Mollic Vertisol* (*Pellic*).

TABLE 32.8   The Key to the RSGs of the WRB

Soils having organic material, either

1. Ten centimeters or more thick starting at the soil surface and immediately overlying ice, continuous rock, or fragmental materials, the interstices of which are filled with organic material or
2. Cumulatively within 100 cm of the soil surface either 60 cm or more thick if 75% (by volume) or more of the material consists of moss fibers or 40 cm or more thick in other materials and starting within 40 cm of the soil surface

Histosols (HS)

Other soils having

1. Either a hortic, irragric, plaggic, or terric horizon 50 cm or more thick or
2. An anthraquic horizon and an underlying hydragric horizon with a combined thickness of 50 cm or more

Anthrosols (AT)

Other soils having

1. Twenty percent or more (by volume, by weighted average) artifacts in the upper 100 cm from the soil surface or to continuous rock or a cemented or indurated layer, whichever is shallower or
2. A continuous, very slowly permeable to impermeable, constructed geomembrane of any thickness starting within 100 cm of the soil surface or
3. Technic hard rock starting within 5 cm of the soil surface and covering 95% or more of the horizontal extent of the soil

Technosols (TC)

Other soils having

1. A cryic horizon starting within 100 cm of the soil surface or
2. A cryic horizon starting within 200 cm of the soil surface and evidence of cryoturbation in some layer within 100 cm of the soil surface

Cryosols (CR)

Other soils having

1. One of the following:
   a. Limitation of depth by continuous rock within 25 cm of the soil surface or
   b. Less than 20% (by volume) fine earth averaged over a depth of 75 cm from the soil surface or to continuous rock, whichever is shallower and
2. No calcic, gypsic, petrocalcic, petrogypsic, or spodic horizon

Leptosols (LP)

Other soils having

1. A vertic horizon starting within 100 cm of the soil surface
2. After the upper 20 cm have been mixed, 30% or more clay between the soil surface and the vertic horizon throughout and
3. Cracks that open and close periodically

Vertisols (VR)

Other soils having

1. Fluvic material starting within 25 cm of the soil surface and continuing to a depth of 50 cm or more or starting at the lower limit of a plow layer and continuing to a depth of 50 cm or more and
2. No argic, cambic, natric, petroplinthic, or plinthic horizon starting within 50 cm of the soil surface and
3. No layers with andic or vitric properties with a combined thickness of 30 cm or more within 100 cm of the soil surface and starting within 25 cm of the soil surface

Fluvisols (FL)

TABLE 32.8 (continued)   The Key to the RSGs of the WRB

Other soils having a natric horizon starting within 100 cm of the soil surface

Solonetz (SN)

Other soils having

 1. A salic horizon starting within 50 cm of the soil surface and
 2. No thionic horizon starting within 50 cm of the soil surface

Solonchaks (SC)

Other soils having

 1. Within 50 cm of the mineral soil surface a layer, 25 cm or more thick, that has reducing conditions in some parts and a gleyic color pattern throughout and
 2. No layers with andic or vitric properties with a combined thickness of either
    a. Thirty centimeters or more within 100 cm of the soil surface and starting within 25 cm of the soil surface or
    b. Sixty percent or more of the entire thickness of the soil when continuous rock or a cemented or indurated layer is starting between 25 and 50 cm from the soil surface

Gleysols (GL)

Other soils having

 1. One or more layers with andic or vitric properties with a combined thickness of either
    a. Thirty centimeters or more within 100 cm of the soil surface and starting within 25 cm of the soil surface or
    b. Sixty percent or more of the entire thickness of the soil when continuous rock or a cemented or indurated layer is starting between 25 and 50 cm from the soil surface and
 2. No argic, ferralic, petroplinthic, pisoplinthic, plinthic, or spodic horizon (unless buried deeper than 50 cm)

Andosols (AN)

Other soils having a spodic horizon starting within 200 cm of the mineral soil surface

Podzols (PZ)

Other soils having either

 1. A plinthic, petroplinthic, or pisoplinthic horizon starting within 50 cm of the soil surface or
 2. A plinthic horizon starting within 100 cm of the soil surface and, directly above, a layer 10 cm or more thick, that has in some parts reducing conditions for some time during the year and in half or more of the soil volume, single or in combination
    a. A stagnic color pattern or
    b. An albic horizon

Plinthosols (PL)

Other soils having

 1. A nitic horizon starting within 100 cm of the soil surface
 2. Gradual to diffuse horizon boundaries between the soil surface and the nitic horizon
 3. No ferric, petroplinthic, pisoplinthic, plinthic, or vertic horizon starting within 100 cm of the soil surface and
 4. No gleyic or stagnic color pattern starting within 100 cm of the soil surface

Nitisols (NT)

TABLE 32.8 (continued)   The Key to the RSGs of the WRB

Other soils having

 1. A ferralic horizon starting within 150 cm of the soil surface
 2. No argic horizon that has, in the upper 30 cm, 10% or more water-dispersible clay unless the upper 30 cm of the argic horizon has one or both of the following:
    a. Geric properties or
    b. 1.4 % or more organic carbon

Ferralsols (FR)

Other soils having

 1. An abrupt textural change within 100 cm of the soil surface and, directly above or below, a layer 5 cm or more thick that has in some parts reducing conditions for some time during the year and in half or more of the soil volume, single or in combination
    a. A stagnic color pattern or
    b. An albic horizon and
 2. No albeluvic tonguing starting within 100 cm of the soil surface

Planosols (PL)

Other soils having

 1. Within 50 cm of the mineral soil surface in some parts reducing conditions for some time during the year and in half or more of the soil volume, single or in combination
    a. A stagnic color pattern or
    b. An albic horizon and
 2. No albeluvic tonguing starting within 100 cm of the soil surface

Stagnosols (ST)

Other soils having

 1. A mollic horizon
 2. A Munsell chroma, moist, of 2 or less from the soil surface to a depth of 20 cm or more or having this chroma directly below any plow layer that is 20 cm or more deep
 3. A calcic horizon or concentrations of secondary carbonates starting within 50 cm below the lower limit of the mollic horizon and, if present, above a cemented or indurated layer and
 4. A base saturation (by 1 M NH_4OAc) of 50% or more from the soil surface to the calcic horizon or the concentrations of secondary carbonates throughout

Chernozems (CH)

Other soils having

 1. A mollic horizon
 2. A calcic horizon or concentrations of secondary carbonates starting within 50 cm below the lower limit of the mollic horizon and, if present, above a cemented or indurated layer and
 3. A base saturation (by 1 M NH_4OAc) of 50% or more from the soil surface to the calcic horizon or the concentrations of secondary carbonates throughout

Kastanozems (KS)

Other soils having

 1. A mollic horizon and
 2. A base saturation (by 1 M NH_4OAc) of 50% or more throughout to a depth of 100 cm or more from the soil surface or to continuous rock or a cemented or indurated layer, whichever is shallower

Phaeozems (PH)

TABLE 32.8 (continued)   The Key to the RSGs of the WRB

Other soils having

1. A petrogypsic horizon starting within 100 cm of the soil surface or
2. A gypsic horizon starting within 100 cm of the soil surface and no argic horizon unless the argic horizon is permeated with gypsum or calcium carbonate

Gypsisols (GY)

Other soils having a petroduric or duric horizon starting within 100 cm of the soil surface

Durisols (DU)

Other soils having

1. A petrocalcic horizon starting within 100 cm of the soil surface or
2. A calcic horizon starting within 100 cm of the soil surface and no argic horizon unless the argic horizon is permeated with calcium carbonate

Calcisols (CL)

Other soils having an argic horizon starting within 100 cm of the soil surface with albeluvic tonguing at its upper boundary

Albeluvisols (AB)

Other soils having

1. An argic horizon, which has a CEC (by 1 M NH_4OAc) of 24 $cmol_c$ kg^{-1} clay or more throughout or to a depth of 50 cm below its upper limit, whichever is shallower, either starting within 100 cm of the soil surface or within 200 cm of the soil surface if the argic horizon is overlain by loamy sand or coarser textures throughout and
2. A base saturation (by 1 M NH_4OAc) of less than 50% in the major part between 50 and 100 cm

Alisols (AL)

Other soils having

1. An argic horizon that has a CEC (by 1 M NH_4OAc) of less than 24 $cmol_c$ kg^{-1} clay in some part to a maximum depth of 50 cm below its upper limit, either starting within 100 cm of the soil surface or within 200 cm of the soil surface if the argic horizon is overlain by loamy sand or coarser textures throughout, and
2. A base saturation (by 1 M NH_4OAc) of less than 50% in the major part between 50 and 100 cm

Acrisols (AC)

Other soils having an argic horizon with a CEC (by 1 M NH_4OAc) of 24 $cmol_c$ kg^{-1} clay or more throughout or to a depth of 50 cm below its upper limit, whichever is shallower, either starting within 100 cm of the soil surface or within 200 cm of the soil surface if the argic horizon is overlain by loamy sand or coarser textures throughout

Luvisols (LV)

Other soils having an argic horizon, either starting within 100 cm of the soil surface or within 200 cm of the soil surface if the argic horizon is overlain by loamy sand or coarser textures throughout

Lixisols (LX)

Other soils having an umbric or mollic horizon

Umbrisols (UM)

TABLE 32.8 (continued)   The Key to the RSGs of the WRB

Other soils having

1. A weighted average texture of loamy sand or coarser, if cumulative layers of finer texture are less than 15 cm thick, either to a depth of 100 cm from the soil surface or to a petroplinthic, pisoplinthic, plinthic, or salic horizon starting between 50 and 100 cm from the soil surface
2. Less than 40% (by volume) of gravels or coarser fragments in all layers within 100 cm of the soil surface or to a petroplinthic, pisoplinthic, plinthic, or salic horizon starting between 50 and 100 cm from the soil surface
3. No fragic, irragric, hortic, plaggic, or terric horizon and
4. No layers with andic or vitric properties with a combined thickness of 15 cm or more

Arenosols (AR)

Other soils having

1. A cambic horizon starting within 50 cm of the soil surface and having its base 25 cm or more below the soil surface or 15 cm or more below any plow layer
2. An anthraquic, hortic, hydragric, irragric, plaggic, or terric horizon
3. A fragic, petroplinthic, pisoplinthic, plinthic, salic, thionic, or vertic horizon starting within 100 cm of the soil surface or
4. One or more layers with andic or vitric properties with a combined thickness of 15 cm or more within 100 cm of the soil surface

Cambisols (CM)

Other soils

Regosols (RG)

32.5 The French Systems of Soil Classification

32.5.1 Introduction

The *Commission de Pédologie et de Cartographie des Sols* (CPCS, 1967) issued the French soil classification, building on previous work published by Aubert and Duchaufour (1956), which has been the basis for many soil surveys during the 1970s and 1980s, not only in France but also in many of the former French colonies, notably in Africa. It was replaced by the pedological reference base (PRB; *Référentiel Pédologique Français*) (AFES–INRA, 1990, 1992).

32.5.2 The 1967 CPCS System

The CPCS soil classification system comprises four main levels: the class (*classe*), the subclass (*sous-classe*), the group (*groupe*), and the subgroup (*sous-groupe*); followed by four minor levels: the family (*famille*), the series (*série*), the type (*type*), and the phase (*phase*). However, due to the limited knowledge at the time of design of the system, the four minor levels have not been developed for all classes.

The class comprises soils that have main characteristics in common, such as a certain degree of profile development, weathering mode, composition and distribution of organic matter, and
Diagnostics of the example profile:

Dark, high base surface horizon with sufficient structure and organic carbon to satisfy the *mollic horizon*

Vertic subsurface horizon with slickensides and wedge-shaped aggregates and deep, wide cracks

Calcic horizon with sufficient amount (≥15%) of secondary CaCO$_3$

Key to the RSGs (according to Table 32.8, Five RSGs Are Not Satisfied before Getting to the Vertisols in the Key)	**Prefix Qualifiers**	**Suffix Qualifiers**
Other soils having 1. A *vertic* horizon starting within 100 cm of the soil surface 2. After the upper 20 cm have been mixed, 30 percent or more clay between the soil surface and the *vertic* horizon throughout 3. Cracks that open and close periodically Vertisols (VR)	Grumic Mazic Technic Endoleptic Salic Gleyic Sodic Stagnic Mollic Gypsic Duric Calcic Haplic	Thionic Albic Manganiferric Ferric Gypsiric Calcaric Humic Hyposalic Hyposodic Mesotrophic Hypereutric Pellic* Chromic Novic

*Pellic: refers to very dark (Munsell value, moist ≤3.5 and a chroma, moist ≤1.5) surface horizon

Full classification and name: *Calcic Mollic Vertisol* (*Pellic*)
(The applying prefix qualifier names are put before the RSG name and applying suffix qualifier names are placed between brackets following the RSG name).

FIGURE 32.1 Example for the classification in the WRB (IUSS WG WRB, 2007).

predominant soil-forming factors (e.g., wetness). The subclass differentiation is related to criteria resulting from climatic factors, which influence, among others, the pedoclimate. The groups are defined according to morphological characteristics corresponding to soil development, while the subgroup is differentiated either on degree of intensity of the fundamental evolutionary characteristics or on the presence of important secondary soil-forming processes.

In total, 12 classes are distinguished, namely, nondeveloped mineral soils (sols minéraux bruts), slightly developed soils (sols peu évolués), Vertisols, Andosols, Ca/Mg-saturated soils (sols calcimagnésiques), humus-rich soils (sols isohumiques), brunified soils (sols brunifiés), podzolized soils (sols podzolisés), soils rich in Fe (sols sesquioxides de fer), ferralitic soils, hydromorphic soils, and sodic soils.

Nondeveloped mineral soils (*sols minéraux bruts*) show very little trace of soil development apart from some accumulation of organic matter at the surface. They are characterized by an (A)C, (A)R, or R horizon sequence. Included in this class are eroded soils (Lithosols, Régosols), alluvial, colluvial and eolian accumulations, volcanic deposits, manmade soils, nondeveloped soils in the arctic regions (Cryosols), and nondeveloped desert soils.

The class of *slightly developed (sols peu évolués)* soils has higher organic matter content than the nondeveloped soils and is characterized by an AC or AR horizon sequence. No B horizon is permitted in this class. Included are soils from the arctic regions, with or without permafrost, soils with high organic matter content directly overlying hard rock (rankers, soils over limestone, and slightly weathered soils on volcanic ashes), slightly developed desert soils, and soils resulting from erosion and deposition.

Vertisols are described as clayey soils, which are homogenized or irregularly differentiated as a result of internal movement and which are dominated by swell/shrink clays. The normal horizon sequence is A(B)C, A(B)gC, or A(B)Cg. Subdivision into subclasses and groups is based on external drainage factors and type of structure in the surface horizon (rounded or angular).

Andosols are defined as soils in which the mineral fraction is dominated by poorly crystalline minerals and/or metal humus complexes, associated with variable, but usually high amounts of organic matter.

The *Ca/Mg-saturated soils* (*sols calcimagnésiques*) have an exchange complex, 90% of which is saturated with Ca and/or Mg, and have a pH above 6.8. They are generally associated with calcareous or basic rocks, and have an AR, AC, A(B)R, or A(B)C horizon sequence. They are subdivided into (1) carbonate-rich soils (rendzinas, cryptorendzinas, and brown calcareous soils), (2) saturated soils (soils containing only traces of primary $CaCO_3$ in the fine earth fraction), and (3) gypsiferous soils.

The class of *humus-rich soils* (*sols isohumiques*) comprises soils characterized by a moderate to high accumulation of well-humified, polymerized organic matter. Normally, base saturation is high with Ca as dominant cation, followed by Mg and, sometimes, Na. If the base saturation is only moderate (50%–80%) in the upper part of the soil, it increases with depth. Profile evolution is slight to moderate, with an A(B)C or ABC, rarely AC horizon sequence. Subdivision of these soils (Brunizems, Chernozems, Chestnut soils, Brown soils Sierozems), is based at subclass level on pedoclimatic characteristics.

Brunified (*sols brunifiés*) soils are well-developed soils with an A(B)C or ABC horizon sequence and are characterized by the presence of dominantly mull-type humus. They may have a structural or textural B horizon. Subdivision is based on climate (humid temperate, continental temperate, boreal, or tropical) and the morphology of the profile, giving rise to the groups of brown soils (with a structural B horizon), eluvial soils (with a textural B horizon), gray wooded soils, dernopodzolic soils, eluvial boreal soils, and eutrophic brown tropical soils.

The class of *podzolic soils* (*sols podzolisés*) is characterized by the processes of alteration and destruction of the silicate minerals by fulvic acids and complexation of liberated Fe and Al. These processes result morphologically in a strongly depleted and light-colored eluvial horizon and an illuvial horizon, which has a higher organic matter content than the eluvial horizon and a sesquioxide content, which is higher than the original material. Division at subclass level is based on climatic or pedoclimatic characteristics.

Soils rich in Fe (*sols sesquioxydes de fer*) have an ABC or A(B)C profile characterized by the presence of Fe and/or Mn (hydr) oxides giving the soils characteristic red, yellow, rusty brown, or even black (in the case of Mn) colors, an SiO_2/Al_2O_3 ratio of >2, a base saturation of >50%, and a low amount of organic matter. Two subclasses are recognized, one in which the role of sesquioxides is dominant (ferruginous tropical soils) and another in which the behavior of the clay fraction predominates (fersiallitic soils).

The ferralitic soils are characterized by complete weathering of primary minerals, residual enrichment of resistant minerals (quartz, rutile, etc.), loss of nutrients, and the presence of neo-formations such as kaolinite, gibbsite, goethite, hematite, etc. Subclasses are distinguished on the degree of leaching.

The *class of hydromorphic soils* comprises both organic and mineral soils. The three subclasses are separated on organic matter content. The first subclass (hydromorphic organic soils) is defined as having >30% organic matter over a depth of at least 40 cm if the mineral component is clayey or >20% if the mineral component is sandy. The second subclass (moderately organic hydromorphic soils) has between 8% and 30% organic matter over at least 20 cm depth; while the third subclass, the mineral soils (weakly organic hydromorphic soils) have <8% organic matter over a depth of at least 20 cm. The organic hydromorphic soils are at group level separated on decomposition rate (weak or fibric, moderate or hemic, or strong or sapric), while the two other subclasses are divided on the character of hydromorphism (gley or stagnogley) and accumulation of Fe, $CaCO_3$, or gypsum.

The sodic soils comprise both soils that have a high amount of soluble salts as well as soils with a high exchangeable sodium percentage (ESP). This difference is used to separate the subclasses into sodic soils with a nondegraded structure, comprising the saline soils (solonchak) with an AC horizon sequence, and sodic soils with a degraded structure, having an A(B)C or ABC horizon sequence and comprising alkaline saline soils (high ESP), sodic soils with a textural B horizon (solonetz), and so-called solodized solonetz, which are acid at the surface.

32.5.3 The Pedological Reference Base (*Référentiel Pédologique Français*)

This differs basically from the older CPCS system, which it replaces, in that it is being presented as a reference system, not a hierarchical classification (AFES–INRA, 1992). It considers the soil mantles as objects of study for which three sets of data are required: (1) the composition of the soil mantle (mineral, organic, etc.), (2) the internal arrangement of the individual constituents (e.g., structure), and (3) the soil dynamics (e.g., evolution over time).

At the highest level, the PRB recognizes the pedological system, which comprises several associated horizons grouped in a 3D space pattern. A horizon is defined as a part of the soil mantle, which can be considered homogenous. Because dimensions of horizons and pedological systems are not infinite, vertically and laterally, they merge into other systems (e.g., bedrock or other pedological systems).

The authors of the PRB have tried to design a system, which, at the same time, is both scientific and practical as well as precise but flexible. An example of this is the depth indications used in the descriptions of the horizons; the PRB starts off with the tolerance limits concerning depth or thickness requirements, for example, 10 cm must be considered as 5–15 cm, 40 cm means 30–50 cm, etc. Therefore, only two categories are distinguished—the references and the types, the latter being indicated by one or more qualifiers. The reference horizons form the basis of the system. So far, 50 have been proposed (AFES–INRA, 1992), defined, and described by several of the following: (1) morphological characteristics (constituents, pedological features, etc.), (2) analytical data, (3) pedogenetic significance, (4) major possible variations of the characteristics, and (5) most common positions within soil mantles. A succession or combination of reference horizons identifies a diagnostic solum and permits the association of such a solum with a reference. The PRB has proposed some 90 references (Table 32.9). Several of

TABLE 32.9 Major Groupings of References (MGR) and References of the AFES–INRA Pedological Reference Base

MGR	Reference	Brief Description
Alocrisols	Typic Alocrisols	Very acid, brown or yellow soils with a high amount of exchangeable aluminum ($2–8\,cmol_c\,kg^{-1}$ fine earth and Al saturation of 20%–50%)
	Humic Alocrisols	Very acid, brown or yellow soils with a thick, dark colored surface horizon high in organic matter and a high amount of exchangeable aluminum
Alu-Andisols	Humic Alu-Andisols	Non-allophanic soils in weathered volcanic deposits having a thick surface horizon rich in organic matter
	Typic Alu-Andisols	Soils in volcanic deposits or strongly weathered ferralitic material having an aluminum-rich surface horizon and an allophane-dominated subsurface horizon
Andosols	Humic Andosols	Allophane-rich soils having a thick surface horizon rich in organic matter
	Eutric Andosols	Allophane-rich soils having a surface horizon with base saturation > 50%
	Dystric Andosols	Allophane-rich soils having a surface horizon with base saturation < 50%
	Perhydrated Andosols	Allophane-rich soils having a high irreversible water content
Anthroposols	Transformed Anthroposols	Soils modified by intensive or long-continued human activities
	Artificial Anthroposols	Man-made soils consisting of non-soil material (mine refuse, urban debris, etc.)
	Reshaped Anthrosols	Man-made soils consisting of transported soil material
Arenosols	Arenosols	Deep (>120 cm) sandy soils
Brunisols	Saturated Brunisols	Non-calcareous soils with a structural B horizon and 80%–100% base saturation
	Meso-saturated Brunisols	Non-calcareous soils with a structural B horizon and 50%–80% base saturation
	Oligo-saturated Brunisols	Non-calcareous soils with a structural B horizon and 20%–50% base saturation
	Resaturated Brunisols	Non-calcareous soils with a structural B horizon and >80% base saturation due to cultivation
Calcarisols	Calcarisols	Soils with a calcic horizon at least 10 cm thick, starting within 20 cm depth
Calcisols	Calcisols	Soils with non-calcareous, base-saturated (mainly Ca^{2+}) A and B horizons
Calcosols	Calcosols	Soils with calcareous A and B horizons ($CaCO_3$ > 5%)
Castanosols	Castanosols	Soils with a moderately thick to thick, dark colored, base-saturated surface horizon rich in organic matter
Chernosols	Chernosols	Soils with a thick, very dark colored, base-saturated surface horizon rich in organic matter
Colluviosols	Colluviosols	Soils in colluvial deposits
Cryosols	Histic cryosols	Soils with permafrost within 1 m depth and a histic surface horizon
	Mineral cryosols	Soils with permafrost within 2 m depth lacking a histic surface horizon
Dolomitosols	Dolomitosols	Soils with dolomitic A and B horizons (molar ratio of $CaCO_3/MgCO_3$ < 1.5)
Ferrallisols	Soft Ferrallisols	Strongly weathered soils with a ferralitic or oxidic mineralogy
	Nodular Ferrallisols	Strongly weathered soils with a high amount of sesquioxide nodules
	Petroxydic Ferrallisols	Strongly weathered soils with indurated sesquioxide layers (e.g., cuirasses)
Fersialsols	Carbonated Fersialsols	Calcareous soils with significant amounts of 2:1 clays and "free iron"
	Saturated Fersialsols	Base-saturated soils with significant amounts of 2:1 clays and "free Fe"
	Desaturated Fersialsols	Desaturated soils with significant amounts of 2:1 clays and "free Fe"
	Xanthic Fersialsols	Yellowish soils with significant amounts of 2:1 clays and "free Fe"
Fluviosols and thalassosols	Raw Fluviosols	Soils in fluviatile deposits lacking any horizon development
	Typical Fluviosols	Soils in fluviatile deposits with one or more not fully developed reference horizons
	Brunified Fluviosols	Soils in fluviatile deposits with a well-developed structural B horizon
	Thalassosols	Non- or weakly developed soils in marine or fluvio-marine deposits
Gypsosols	Gypsosols	Soils with accumulation of gypsum
Histosols	Leptic Histosols	Shallow organic soils with consolidated or unconsolidated rock within 40 cm
	Fibric Histosols	Organic soils with weakly decomposed organic material more than 60 cm thick
	Mesic Histosols	Organic soils with moderately decomposed organic material more than 40 cm thick
	Sapric Histosols	Organic soils with strongly decomposed organic material more than 40 cm thick
	Composite Histosols	Organic soils without dominance of either fibric, mesic, or sapric materials between 40 and 120 cm
	Covered Histosols	Organic soils with a cover of mineral soil material 10–40 cm thick
	Floating Histosols	Organic soils on water occurring between 40 and 160 cm depth
Lithosols	Lithosols	Shallow soils (<10 cm) over continuous hard rock or indurated layer
Luvisols	Neoluvisols	Soils with a moderately developed eluvial and well developed textural B horizon
	Typic Luvisols	Soils with a well-developed eluvial and textural B horizon
	Degraded Luvisols	Soils with a well-developed, partially light colored and hydromorphic eluvial horizon penetrating a gleyed textural B horizon

TABLE 32.9 (continued)   Major Groupings of References (MGR) and References of the AFES–INRA Pedological Reference Base

MGR	Reference	Brief Description
	Dernic Luvisols	Soils with a well-developed, partially light colored eluvial horizon penetrating a textural B horizon
	Truncated Luvisols	Soils with a textural B horizon but lacking an eluvial horizon
Magnesisols	Magnesisols	Soils with non-calcareous, base-saturated ($Ca^{2+}/Mg^{2+} < 2$) A and B horizons
Organosols	Calcaric Organosols	Well-drained, organic matter rich (>8% organic C), calcareous soils directly overlying an unconsolidated or consolidated substratum
	Saturated Organosols	Well-drained, organic matter rich (>8% organic C), base-saturated ($Ca^{2+}/Mg^{2+} > 5$) soils directly overlying an unconsolidated or consolidated substratum
	Undersaturated Organosols	Well-drained, organic matter rich (>8% organic C), undersaturated (BS < 80%) soils directly overlying an unconsolidated or consolidated substratum
	Tangelic Organosols	Well-drained, organic matter rich (>8% organic C), base-saturated soils with a thick, greasy horizon consisting of soil animal casts ("tangel horizon")
Pelosols	Typic Pelosols	Clay-rich, slightly weathered soils lacking coloration in the B horizon
	Brunified Pelosols	Clay-rich, slightly weathered soils with a brown colored B horizon
	Differentiated Pelosols	Clay-rich, slightly weathered soils with a clear eluvial horizon
Peyrosols	Stony Peyrosols	Soils which have throughout the upper 50 cm 40% or more stones plus 20% or more other coarse fragments
	Gravelly Peyrosols	Soils which have throughout the upper 50 cm 60% or more gravel, stones and boulders, but less than 40% stones
Planosols	Typic Planosols	Soils with abrupt textural change and temporary perched watertable within 50 cm
	Distal Planosols	Soils with abrupt textural change and temporary perched watertable below 50 cm
	Structural Planosols	Soils with a temporary perched watertable within 50 cm of the surface caused an impermeable layer which is not texturally induced (e.g., fragipan, duripan)
Podzosols	Duric Podzosols	Soils with an eluvial horizon and a cemented podzol B horizon
	Humo-Duric Podzosols	Soils with an indurated podzol B horizon, lacking an eluvial horizon
	Soft Podzosols	Soils with an eluvial horizon and a soft podzol B horizon
	Placic Podzosols	Soils with podzol B horizon and a placic horizon
	Ochric Podzosols	Soils with a weakly developed humic podzol B horizon, lacking an eluvial horizon
	Humic Podzosols	Soils with a soft humic podzol B horizon, lacking an eluvial horizon
	Post_Podzosols	Man-modified soils in which (remnants of) the podzol B horizon can be recognized
	Eluvial Podzosols	Soils lacking a podzol B horizon, but having lateral linkage to a podzol B horizon
Rankosols	Rankosols	Soils with a moderately thick A horizon with non-calcareous coarse fragments overlying consolidated or unconsolidated rock
Reductisols and redoxisols	Typic Reductisols	Hydromorphic soils conditioned by saturation of fluctuating groundwater table
	Stagnic Reductisols	Hydromorphic soils conditioned by a perched water table
	Duplex Reductisols	Hydromorphic soils conditioned by groundwater and stagnating surface water
	Redoxisols	Soils with a textural discontinuity and a perched water table
Regosols	Regosols	Shallow soils (<10 cm) over unconsolidated material or only slightly coherent rock
Rendisols	Rendisols	Soils with non-calcareous, base-saturated (mainly Ca^{2+}) A horizon over consolidated or unconsolidated calcareous rock
Rendosols	Rendosols	Soils with deep (>30 cm) calcareous A horizon ($CaCO_3$ > 5%) over consolidated or unconsolidated calcareous rock
Salisols	Chloridi-Sulfatic Salisols	Neutral soils with a high amount of sodium, magnesium or calcium salts
	Carbonatic Salisols	Alkaline soils with a high amount of carbonate/bicarbonates
Sodisols	Undifferentiated Sodisols	Alkaline soils with a high amount of exchangeable sodium
	Solonetzic Sodisols	Soils with clay illuviation and moderate leaching of sodium in the upper part
	Solodic Sodisols	Soils with clay illuviation and strong leaching of sodium in the upper part
Sulfatosols	Sulfatosols	Very acid soils with jarosite within 50 cm depth
Thiosols	Thiosols	Waterlogged soils containing sulfide minerals, rapidly acidifying upon aeration
Veracrisols	Veracrisols	Soils with a thick (50–150 cm), acid, dark colored surface horizon with a high biological activity overlying a slowly permeable horizon (e.g., textural B horizon)
Vertisols	Topovertisols	Deep, clayey soils in level, low-lying positions which crack and show gilgai microrelief, slick
Vitrandisols	Vitrandisols	Soils in slightly weathered pyroclastic material
Yermosols	Yermosols	Hot desert soils

these are closely associated with each other because, for example, they may have the same reference horizons. Such references are described together as major groupings of references to avoid duplication and to associate the references with traditional pedological concepts. For example, the Podzosols major grouping of references comprises seven references characterized by a process of podzolization. However, major groupings of references do not form part of the PRB.

32.6 The Soil Classification System of Russia

32.6.1 The Soil Classification System of the Former USSR

32.6.1.1 Introduction

This system was available for soil survey from 1967 as a technical document. An official revised version was published in Russian in 1977 and in English in 1986 (VASKhNIL, 1986). This classification serves as a manual for soil examination and survey in many countries of the former USSR, for governmental assessment of land records and evaluation, as well as a reference book on agricultural and industrial planning for agronomists, land use planners, reclamation specialists, and others. It was amended (Shishov and Sokolov, 1990) to correct obvious errors and to integrate new knowledge and data. The taxonomic levels of the classification system are expanded and new names have been introduced for a number of soils.

32.6.1.2 Structure of the System

The soils are not defined as sequences of diagnostic horizons with fixed frames of properties, like in many other systems. Every soil type has a description of a "central concept," a typical profile. Profound knowledge of the soil-forming processes is required in order to recognize and classify the soils. The higher levels are known as types, subtypes, genera, and species. At subtype level, apart from subtypes with overlapping soil-forming process, the facies modifier may be added to indicate the thermal regime. Twenty-seven of these facies are recognized, ranging from arctic permafrost to subtropical hot nonfreezing.

32.6.1.3 Brief Description of the Types

Some 71 soil types are distinguished at the highest level and are characterized as follows:

Podzolic soils are characterized by either downward movement of organic acids facilitating decomposition of primary and secondary minerals and removal of weathering products or downward movement of clay particles.

Bog-podzolic soils have a combination of downward movement of organic acids or clay particles with either stagnating water conditions in the upper part of the soil or groundwater affecting the bottom part, resulting in a

bleached eluvial horizon and hydromorphic properties in both the eluvial and illuvial horizons. Some of these soils have a peaty layer at the surface.

Sod-calcareous soils have a dark-colored, base-saturated, and humus-rich surface horizon overlying calcareous parent material.

Sod-gley soils are poorly drained with a dark, humus-rich surface horizon and hydromorphic features at shallow depth.

Gray forest soils have a dark-colored, humus-rich surface horizon of variable thickness with a bleached horizon or conspicuous white powdery spots overlying a clay-illuviated subsurface horizon.

Gley gray forest soils are similar to those above but with distinct hydromorphic features below the surface horizon.

Brown forest soils (*or Burozems*) have well-developed nut-like structure and intensive brownish and yellow color in B horizon combined with certain enrichment with organic matter in the surface horizon(s).

Gley brown forest soils (*or Gley burozems*) are similar to those above except for clear hydromorphic features below the surface horizon.

Podzolic brown forest soils (*or Podzolic burozems*) have a clearly developed eluvial horizon, clay-illuvial horizon, and weak hydromorphism due to seasonal surface waterlogging.

Gley podzolic brown forest soils (*or Gley podzolic burozems*) are similar to those above, but with seasonal wetness more pronounced. The process of acidic hydrolysis may take place in the upper part of these soils.

Bleached meadow soils (*Podbels*) are seasonally waterlogged with a bleached horizon near the surface, in which segregation of Fe in concretions is the main ongoing process.

Meadow chernozem-like soils have a thick, dark-colored, and humus-rich surface horizon and distinct features of hydromorphism (gray and rusty colors, Fe/Mn concretions, white powdery coatings) in the lower part of the soils, with no evidence of secondary carbonates.

Chernozem-like dark meadow soils are waterlogged with a peaty or mucky surface horizon overlying a dark-colored, humus-rich mineral horizon with rust colored mottles.

Chernozems are well-drained, base-saturated, or only slightly undersaturated soils with a thick, dark-colored surface horizon rich in organic matter and accumulation of illuvial secondary carbonates.

Meadow-chernozem soils are similar to those above, but with some features of wetness in the lower part of the solum.

Chestnut soils are well-drained and base-saturated with a dark-colored surface horizon, which is less thick and less rich in organic matter than in chernozems. The lower part of the solum often contains accumulations of calcium carbonate and/or gypsum.

Meadow chestnut soils are similar as the soils above, but with distinct features of wetness in the lower part of the solum.

Meadow soils are conditioned by a brief period of surface waterlogging and a longer period of saturation by groundwater, resulting in humus-rich surface horizons overlying a gleyed subsoil.

Semidesert brown soils have an accumulation of calcium carbonate, possibly overlying accumulations of gypsum and a crusty surface horizon.

Semidesert meadow brown soils are similar to those above, but with a higher organic matter content, weak signs of hydromorphism, and deeper $CaCO_3$ accumulations.

Desert gray brown soils are calcareous with a low organic matter content and a variable degree of salinization.

Desert takyr-like soils are weakly developed with a friable porous surface crust.

Takyrs have a hard, porous but crusted surface horizon cracking into polygonal patterns.

Desert sandy soils are coarse textured with little horizon differentiation apart from some accumulation of organic matter and segregation of calcium carbonate at depth.

Meadow desert soils are poorly differentiated, characterized by enrichment with organic matter at the surface and signs of hydromorphism in the subsoil.

Serozems have a shallow gray humus-enriched horizon and a calcareous illuvial layer in the subsoil.

Meadow-serozem soils are similar to those above, but signs of wetness occur in the deeper subsoil.

Semidesert and desert meadow soils have periodic or permanent wetness through capillary rise reaching the surface, giving rise to a well-developed, humus-rich surface horizon and a gleyed subsoil, in which carbonate concentrations are linked to the groundwater level.

Irrigated soils include a variety of types, which are all related to the original soil (irrigated serozems, irrigated brown soils, irrigated meadow brown soils, irrigated gray brown soils, irrigated takyr-like soils, irrigated meadow desert soils, irrigated meadow soils, and irrigated bog soils), in which irrigation has caused considerable modification including enhancement of biological activity, leaching, accumulation of sediments from irrigation water, enrichment in carbonates and soluble salts, etc.

Gray-cinnamon brown soils have a well-developed surface horizon with a low amount of organic matter and a clay-enriched subsurface horizon. The soils are calcareous throughout and differ from chestnut soils in that they do not freeze during wintertime.

Meadow gray-cinnamon brown soils are similar to those above, but with clear indications of increased wetness in the subsoil.

Cinnamon brown soils are deep with a high amount of organic matter, a clay-enriched subsurface horizon with a characteristic cinnamon brown color, and secondary carbonates accumulation.

Meadow cinnamon brown soils are similar to those above, but with clear indications of increased wetness in the subsoil.

Gray meadow forest soils have a thick, humus-enriched surface horizon and hydromorphic features starting at or near to the surface.

Zheltozems are leached subtropical soils with no or only weak textural differentiation and rich in sesquioxides.

Gley zheltozems are similar to those above, but with pronounced gleying throughout the profile.

Podzolic–zheltozem soils are leached subtropical soils with clear textural differentiation and a high content in sesquioxides. Gley features are common in the transition zone between the eluvial and illuvial horizons.

Podzolic–zheltozem gley soils are similar to those above, but with pronounced gleying throughout the profile, resulting in the accumulation of Fe in the illuvial horizon.

Krasnozems are strongly weathered subtropical soils with a high amount of sesquioxides. The clay fraction mainly contains kaolinite, halloysite, goethite, and gibbsite.

Peat-bog soils are a group that includes two soil types, high peat-bog soils and low peat-bog-soils. Both are waterlogged organic soils, the first type forming in upland positions and fed with rainwater, the second one—in lowland positions and fed with groundwater.

Reclaimed peat soils include corresponding two types that are drained peat soils with a plow layer.

Meadow-bog soils are waterlogged mineral soils with or without a shallow organic layer at the surface.

Bog soils of the semideserts and deserts have shallow groundwater (usually <50 cm) and an organic matter-rich surface horizon in desert or semidesert conditions.

Solods are degraded solonetzes and solonetzic soils of which the upper horizons are acidified, resulting in a well-differentiated soil with a humus-rich surface horizon, a white eluvial horizon, and a brownish colored, compact illuvial B horizon.

Solonetzes conform a group of types that have a high amount of exchangeable Na, an (near) absence of readily soluble salts, resulting in a well-expressed eluvial horizon and a compact illuvial horizon. There are three types in this group: automorphic (related to the parent material), semihydromorphic, and hydromorphic (related to groundwater influence) solonetzes.

Solonchaks have a high amount of soluble salts. Two soil types, automorphic and hydromorphic solonchaks, are distinguished.

Alluvial soils are divided into three main groups: alluvial soils with deep groundwater and only a brief period of flooding (sod alluvial soils), alluvial soils influenced by both flooding and groundwater at moderate (1–2 m)

depth (meadow alluvial soils), and alluvial soils that are conditioned by a long period of flooding or shallow groundwater in combination with surface flooding (bog alluvial soils). In addition, the soil reaction, related to soil zone, is used to further subdivide these groups into types.

Mountain meadow soils occur in cold and moist high mountains, which receive a large excess of moisture resulting in a strongly leaching regime, with an acid soil reaction and a considerable accumulation of organic matter in the surface horizon.

Chernozem-like mountain meadow soils occur in high mountains, which, although receiving an excess in moisture, have only a moderately leaching regime, resulting in a weakly acid to weakly alkaline soil reaction as well as a considerable accumulation of organic matter in the surface horizon.

Mountain meadow-steppe soils develop under similar conditions as above but have a much lower exchange capacity than the chernozem-like mountain meadow soils.

An overview of the types and subtypes distinguished in the 1986 USSR soil classification is given in Table 32.10.

32.6.2 The Soil Classification System of the Russian Federation

32.6.2.1 Introduction

The 1977 classification and diagnostics of soils of USSR (VASKhNIL, 1986) did not satisfy both scientists and practical experts. Just 5 years after its publication, the Dokuchaev Soil Science Institute initiated work on a new version of soil classification. A complete version was published in 1997; an English translation is also available, in an adapted and improved form (Arnold, 2001). The discussion of the classification resulted in its further revision, and soon after, a new version was published (Shishov et al., 2004; see also Krasilnikov et al. 2009) for detailed description and correlation. In the Russian Federation, this system is currently introduced and used along with the older soil classification of the USSR.

32.6.2.2 Structure of the System

Like most actual soil classifications, the Russian taxonomy uses the concept of diagnostic horizons; a unique sequence of genetic diagnostic horizons comprises a soil type. In the Russian classification, the designated horizons are mutually exclusive, which provides more order to the taxonomy; for example, this classification has a key for diagnostic horizons that is impossible in other classifications. Soil types are grouped in sections and trunks. On the lower level, the types are subdivided on the basis of overlapping pedogenetic processes, particular properties, texture, and origin of parent material. The Russian classification stresses the importance of agricultural transformation of soils: soils having minor agrogenic impact are defined as subtypes of

TABLE 32.10 Types and Subtypes of the 1986 USSR Soil Classification

Types	Subtypes
Podzolic soils	Gley-podzolic soils
	True podzolic soils

superficially disturbed soils, those under intensive cultivation enter "agrotypes" within the same section (e.g., *agropodzolic soils* vs. *podzolic soils*), and those completely transformed by agricultural practices are grouped in a special section of Agrozems.

32.6.2.3 Brief Description of the Sections

The classification includes 227 soil types, which are grouped in 27 sections and 3 trunks, defined as follows:

Postlithogenic soils: *a trunk of soils*—bringing together soils where soil-formation processes occur on a previously formed parent material and modern accumulation of matter on the surface is negligible. Includes the following soil sections:

Texture differentiated soils: soils with distinct clay illuviation, expressed both as the difference in clay content between the topsoil and B horizon and as clay coating in the illuvial horizons

Al–Fe–humus soils: soils having illuviation of aluminum and iron in complexes with organic matter

Iron metamorphic soils: soils having a B horizon, altered in situ. The alteration is expressed mainly as iron (hydr) oxides crystallization

Structural metamorphic soils: soils having a B horizon, altered in situ. The alteration is expressed mainly as soil structure modification comparing with that of parent material

Cryometamorphic soils: soils having a B horizon, altered in situ. The alteration is related mainly to the presence of permafrost and the effect of freezing–thawing cycles in the topsoil

Pale metamorphic soils: soils having structural alteration, combined with secondary calcium carbonates and (provisionally) soluble salts accumulation. These soils are geographically related to extracontinental cryoarid regions of Eastern Siberia

Cryoturbated soils: soils formed in the presence of permafrost and affected with soil material cryoturbation due to freezing–thawing cycles in the topsoil

Gleyic soils: soils affected with excessive moisture due to high groundwater level

Humus-accumulating soils: soils having a deep dark, well-structured humus-accumulative topsoil horizon

Light-humus carbonate-accumulating soils: soils having relatively poor and light topsoil, combined with secondary calcium carbonates accumulation

Alkaline clay-differentiated soils: soils with alkaline reaction and with a clay-illuvial horizon

Halomorphic soils: soils with toxic concentrations of soluble salts

Hydrometamorphic soils: soils affected with excessive moisture due to high groundwater level but having no typical "gleyic" (bluish-green) colors due to high organic matter content and/or alkalinity

Organic matter–accumulating soils: soils with no other diagnostic horizons than humus-accumulative one

Eluvial soils: soils with a distinct eluvial (clay and/or iron depleted) horizon but without evidences of clay and iron illuviation beneath

Lithozems: shallow soils (less than 30 cm) with a humus-accumulative horizon

Weakly developed soils: immature soils either in sandy or clayey loose materials or over consolidated rock

Abrazems: strongly eroded soils with exposed B or BC horizon

Agrozems: soils mixed in the course of agricultural management down to the B or BC horizon

Agroabrazems: cultivated soils, previously affected with intensive erosional processes

Turbated soils: soils mixed down to the depth of more than 1 m in the process of land improvement

Sinlithogenic soils: *a trunk of soils*—gathering together the soils, where soil formation occurs in the condition of periodical or continuous accumulation of new material on the surface. It includes the following soil sections:

Alluvial soils: soils formed in actual river valleys in recent alluvial deposits

Volcanic soils: soils formed under influence of recent periodic volcanic ash deposition

Stratozems: include all the soils with periodical eolian or fluvial accumulation of sediments (including long-term irrigation) with no or weak development of soil profile on the surface

Weakly developed soils: soils formed in fresh eolian or fluvial sediments, with incipient pedogenesis

Organogenic soils: *a trunk of soils*—including the soils formed in organic material, mainly in peat. There are two sections within this trunk, namely:

Peat soils: soils formed in organic materials

Torfozems: drained peat soils, in places deeply cultivated and ameliorated with mineral ground

32.7 The Chinese Soil Taxonomic Classification

32.7.1 Introduction

Until 1949, the Chinese soil classification was based on that of the United States but then was replaced by that of the USSR geographical classification (ISS-AS, 1990), and integrating locally important soils, such as long-continued cultivated soils, paddy soils among others. In 1994, a drastically renewed first proposal for a new *Chinese Soil Taxonomic Classification* (CSTC) based largely on *Soil Taxonomy* was issued (Gong, 1994), which is still under review and subject to modification. In developing the CSTC system, many elements of the *Legend of the Soil Map of the World* (FAO–UNESCO, 1974) and other soil classifications were incorporated.

32.7.2 Structure

The CSTC is a hierarchical system with seven categories: order, suborder, group, subgroup, genus, species, and variety. The first four levels are used to construct mapping units for small-scale maps, the lower three for more detailed maps.

The order is based on soil properties, which result from or reflect major soil-forming processes. The suborder is defined according to soil properties, which either control recent soil-forming processes or reflect dominant limiting factors. At group level, intensities of major or secondary soil-forming processes are used to differentiate among the soils, while the subgroup reflects the deviation from the central concept of the group.

The system presently has defined 13 orders, 33 suborders, 78 groups, and 301 subgroups. The nomenclature used is a mixture of older and more recent names, as well as local names for typical Chinese soils. The names of the order and suborder are linked, the group and subgroup nomenclature is different, to avoid names becoming too long. An overview of the orders, suborders, and groups of the Chinese Soil Taxonomic System is given in Table 32.11.

32.7.3 Diagnostic Horizons and Characteristics

Like many other soil classification systems, the Chinese Soil Taxonomic System uses diagnostic horizons and characteristics to identify the soil. A number of the diagnostic horizons are directly taken from other systems, such as the argillic horizon from *Soil Taxonomy*, while others are newly defined to suit Chinese conditions. Thirty diagnostic horizons are defined, 8 surface horizons or epipedons, 10 subsurface horizons, and 12 horizons, which may occupy any position in the soil profile.

Three categories of diagnostic surface horizons are recognized: histic, humus (isohumic, umbrihumic, and ochrihumic epipedons), and anthropic epipedons. Particularly, the latter category has a number of diagnostic epipedons, which do not occur in other systems, namely, the warpic (finely stratified epipedon resulting from long-continued irrigation), cumulic (thick

epipedon resulting from additions of manure and organic-rich soil material), mellowic (epipedon resulting from long and intensive cultivation and applying night soil, organic trash, and manure), and hydragric (epipedon resulting from cultivating the soil under wet conditions) epipedons.

The 10 diagnostic subsurface horizons are the albic (white), weathering B, humilluvic (illuvial organic matter), argillic (clay illuviated), clayific (in situ clay accumulation through weathering of primary minerals), claypan (slowly permeable, clay-rich horizon), alkalic (clay-illuviated horizon with high Na percentage),

spodic (illuviation of amorphous organic compounds in combination with Al and/or Fe), agric (illuviated humus clay or humus silt clay under conditions of cultivation), and hydragric–redoxic (oxidation–reduction horizon related to wet cultivation) horizons.

The other diagnostic horizons comprise the calcic, hypercalcic, gypsic, hypergypsic, salic, hypersalic, sulfuric, phosphic, and gleyic horizons and the calci-, gypsi-, and salipans.

Twenty-three diagnostic characteristics (characters, properties, features, contacts, saturation, materials, regimes, or layers) are defined. These are lithologic characters (features inherited from the parent material), vertic features (shrink/swell phenomena), desertic features (surface and topsoil features related to arid conditions), takyric features (cracking of surface soil in arid conditions induced by wetting and drying), redoxic features (hydromorphism), frost/thaw features, regosolic features (<35% coarse fragments), skeletic features (between 35% and 70% coarse fragments), lithic features (>70% coarse fragments), lithic contact, paralithic contact, siallic properties (weathering B horizon of which the clay fraction is dominated, 2:1 or 2:1:1 clays), fersiallic properties (weathering B horizon of which the clay fraction is dominated 2:1 or 2:1:1 clays and which has ≥2% free Fe oxides), ferralic properties (weathering B horizon of which the clay fraction is dominated 1:1 clays and which has ≥2% free Fe oxides), andic properties (related to weathering of pyroclastic deposits), base saturation, Al saturation, calcaric properties (≥1% $CaCO_3$), humic properties (high organic matter content), organic soil materials, soil moisture regimes, soil temperature regimes, and permafrost layer (perennial temperature at or below 0°C).

When important and obvious properties of soil horizon do not fulfill the combination required for a diagnostic horizon, the CSTC uses the term evidence. They are used to identify soil taxa, particularly at subgroup level. Twelve diagnostic evidences are defined so far, namely, histic, warpic, cumulic, mellowic, clayific (all meeting the requirements of the related diagnostic horizons apart from thickness), alkalic (lower ESP), spodic (lower ratio of pyrophosphate extractable Al + Fe to clay), calcic (either shallower thickness or lower $CaCO_3$ content), gypsic (either shallower thickness or lower gypsum content), salic (lower salt content), gleyic (discontinuous gleyic parts), and vertic (less wider cracks and a clayey subhorizon within 50 cm depth) evidences.

32.8 The Australian Soil Classification

32.8.1 Introduction

In 1996, a new soil classification system for Australia was issued (Isbell, 1996). Until then, two different soil classification systems were widely used (Stace et al., 1968; Northcote, 1979). A soil classification committee has worked over 15 years to develop the new system, taking advantage of the previously used systems, the numerous soil surveys carried out all over the country, and the large database containing data of some 14,000 soil profiles, which was constructed during the time of the committee's work.

32.8.2 Structure and Nomenclature

The new system is multicategorical, comprising orders, suborders, great groups, subgroups, and families. In total, 14 orders are recognized (Anthroposols, Calcarosols, Chromosols, Dermosols, Ferrosols, Hydrosols, Kandosols, Kurosols, Organosols, Podosols, Rudosols, Sodosols, Tenosols, and Vertosols), distinguished by fairly straightforward criteria, which can easily be recognized in the field. Nomenclature is often based on Latin or Greek roots, as with many other modern soil classification systems, but the names are clearly different from *Soil Taxonomy*, the *FAO–UNESCO Legend*, or the *World Reference Base for Soil Resources*, in order to avoid confusion.

Unlike many other soil classification systems, there is no fixed soil depth for classification purposes in the new Australian system. The concept of pedologic organization (McDonald et al., 1990) is used to define the soil to be classified. Isbell (1996) describes this as "… a broad concept used to include all changes in soil material resulting from the effect of the physical, chemical and biological processes that are involved in soil formation." Consequently, soil studies for classification purposes may need to go to considerable depth. At family level, this is recognized since one of the family criteria, soil depth, includes a class Giant for those soils that are deeper than 5 m.

Division of seven orders (Chromosols, Dermosols, Ferrosols, Kandosols, Kurosols, Sodosols, and Vertosols) into suborders is based on color criteria (e.g., red, brown, yellow, gray, and black). Suborders of Anthroposols are distinguished on the kind and nature of the human activity, in Calcarosols, the degree and kind (shells, gypsum, $CaCO_3$) of the accumulation are used for the subdivision, suborders of the Hydrosols reflect the type of tidal inundation, the degree of salinity, and the reduction–oxidation regime, Organosols are classically divided according to the degree of decomposition of the organic material, suborders of the Podosols reflect the degree of wetness, Rudosols are divided according the nature of the material, while, in Tenosols, the type of surface horizon, the occurrence of a bleached horizon, and the presence or absence of a weakly developed B horizon are used to characterize the suborders.

Subdivision of the great groups and subgroups is still incomplete for a number of suborders. For those suborders that are developed into great groups and subgroups, division is generally made on the presence or absence of important diagnostic horizons and materials and on the degree of importance of certain characteristics.

Criteria considered at family level are A horizon thickness (not in Organosols, Rudosols, and Vertosols), gravel content of the surface and A1 horizon (not in Organosols), A1 horizon texture (not in Organosols and Vertosols), B horizon maximum texture (not in Organosols and Rudosols), soil depth (not in Organosols), thickness of the soils above the upper boundary of the Bk horizon (in Calcarosols only), nature of the uppermost organic materials and cumulative thickness of the organic materials (in Organosols only), and clay content of the upper 0.1 m (in Vertosols only).

The full soil name is constructed as follows: subgroup, great group, suborder, order, and family. A unique coding system for all levels is provided for recording the classification of soil profiles. Included in this coding system is the opportunity to indicate a confidence level to the soil classification.

32.8.3 Description of the Orders

The 14 orders now recognized in the Australian soil classification, and their characteristics are as follows, in alphabetical order:

Anthroposols (Gr. anthropos, man): soils resulting from human activities

Calcarosols (L. calcis, lime): soils having pedogenetic carbonate accumulations throughout the solum or at least directly below the A1 or Ap horizon

Chromosols (Gr. chroma, color): soils having a clear or abrupt textural B horizon in which the major part of the upper 0.2 m of the B2 horizon is not strongly acid $[pH_{H_2O} (1:5) \geq 5.5$ and $pH_{CaCl_2} (1:5) \geq 4.6]$

Dermosols (L. dermis, skin): soils having a B2 horizon, which has a structure more developed than weak throughout the major part of the horizon

Ferrosols (L. ferrum, iron): soils having a B2 horizon in which the major part contains >5% free Fe oxide in the fine earth fraction

Hydrosols (Gr. hydor, water): soils that are saturated with water in the major part of the solum for at least 2–3 months in most years. Reducing conditions are not an essential requirement

Kandosols (kandite, 1:1 clay minerals): soils having a well-developed B2 horizon of which the major part is massive or has only a weak grade of structure, and having a maximum clay content in some part of the B2 horizon >15%

Kurosols (no root): soils having a clear or abrupt textural B horizon in which the major part of the upper 0.2 m of the B2 horizon is strongly acid $[pH_{H_2O} (1:5) < 5.5$ and $pH_{CaCl_2} (1:5) < 4.6]$

Organosols (no root): soils having more than 0.4 m of organic materials within the upper 0.8 m or having organic materials from the surface to a minimum depth of 0.1 m overlying either hard rock or other hard layers, partially weathered or decomposed rock or fragmental material with interstices (partially) filled

Podosols (R. pod, under, and zola, ash): soils having a Bs, Bhs, or Bh horizon (horizons with illuvial accumulations of amorphous organic matter Al and Al silica complexes, with or without Fe)

Rudosols (L. rudimentum, a beginning): soils having negligible (or rudimentary) pedological organization apart from the minimal development of an A1 horizon or the presence of less than 10% of B horizon material in fissures in the parent rock or saprolite

Sodosols (E. sodium): soils having a clear or abrupt textural B horizon, in which the major part of the upper

0.2 m of the B2 horizon is sodic (ESP of the fine earth
soil material ≥6)

Tenosols (L. tenius, weak, slight): soils having weak expres-
sion of pedological organization

Vertosols (L. vertere, to turn): soils having ≥35% clay and
developing open cracks, which are at least 5 mm wide
and extend upward to the surface or to the base plow
layer at some time in most years self-mulching hori-
zon, or a thin, surface crust, and having slickensides or
lenticular peds

32.9 The German Soil Classification

32.9.1 Introduction

The latest version of the German soil classification system was
published in 1998 (Bodensystematik, 1998) and updated in 2005
(Ad-hoc-AG Boden, 2005). It is based on the system laid down by
Kubiëna (1953) and Mückenhausen (1962). Older concepts from
the nineteenth and the beginning of the twentieth century using
different approaches will not be discussed in this book. During
recent history, West Germany and East Germany had slightly
differing systems, which were brought together again in 1994.
Responsible for the German classification system is a Working
Group of the German Soil Science Society.

32.9.2 Structure and Nomenclature

The German system is hierarchical with 6 categorical levels
(English terms according to Wittmann, 1997): 4 orders, 21 sub-
orders, 56 types, and 230 subtypes are defined. For the lowest
levels, the varieties and subvarieties, additional (often quantita-
tive) attributes are provided that have to be added to the sub-
type name according to specific rules. For common discussions
among soil scientists, the type or subtype level is used. A key is
available to classify soils down to the type level. The German
system is designed as a natural system, whose structure reflects
the mutual relationships of the units and the inherent architec-
ture of the whole (Kubiëna, 1953).

In addition to classify soils, a system to classify substrates is
provided characterizing texture, coarse fraction, carbonates,
coal, lithogenic carbon, and consolidated and unconsolidated
rock. Usually, soil and substrate classification are given together.

The orders are defined by the water regime: The Terrestrial
soils are dominated by a descending water regime and form
by far the largest order. The Semiterrestrial soils are character-
ized by groundwater influence starting within the first 40 cm
or by groundwater fluctuations over greater depth ranges. The
Semisubhydric and Subhydric soils comprise the soils in tidal
regions and the soils covered by water not exceeding 2 m. The
last order is formed by fens and bogs.

The suborders reflect the stage of soil formation and the
degree of horizon differentiation. They will be described later.

The types are differentiated according to horizons and hori-
zon sequences reflecting specific pedogenic processes and the

properties resulting from these processes (morphogenetic
approach). The allocation of soils requires the knowledge of all
major soil characteristics and the full horizon sequence. Specific
rules apply to fens and bogs and to poorly developed soils,
where characteristics of the parent material are included in the
definition.

Three kinds of subtypes are recognized: The norm sub-
types, the deviation subtypes, and the transition subtypes.
A transition subtype shows some properties of another type.
The names of both types are combined using the name of the
dominant type last. A deviation subtype has some additional
characteristics that are not part of the definition of the type
but fit well within the type. The additional characteristics
are indicated by a prefix added to the name of the soil type.
Finally, the norm subtype lacks both, transition features and
additional features.

Types and subtypes are defined by horizon sequences. A hori-
zon denomination consists of a capital letter as master symbol
followed by one or more lower case letters indicating proper-
ties resulting from soil-forming processes. Lower case letters set
before the master symbol describe geogenic and anthropogenic
characteristics. Most soil characteristics required for the hori-
zon denomination can be recognized in the field.

32.9.3 Description of the Suborders

The 21 suborders recognized in the German soil classification
system are described briefly:

Order Terrestrial Soils

O/C-Böden: soils having an organic horizon overlying
directly continuous rock or coarse material, the inter-
stices of which are filled with organic material

Terrestrische Rohböden: soils having an initial accumula-
tion of organic matter and an initial chemical weather-
ing of the geological parent material

Ah/C-Böden: soils having a fully developed mineral
topsoil horizon enriched with organic matter and
some chemical weathering of the geological parent
material

Schwarzerden: soils having a thick dark mineral topsoil
horizon rich in organic matter with high base satura-
tion and intensive bioturbation and not having a pro-
nounced subsoil horizon

Pelosole: soils originating from parent materials rich in
swelling clays and having a well-developed aggregate
structure without pronounced chemical weathering

Braunerden: soils having a well-developed subsoil horizon
with neoformation of oxides and clay minerals

Lessivés: soils having an accumulation of illuviated clay in
the subsoil

Podsole: soils having an accumulation of illuviated Fe, Al,
and organic matter in the subsoil

Terrae Calcis: soils having a residual accumulation of large
amounts of clay and oxides after limestone weathering

Fersiallitische und Ferrallitische Paläoböden: soils having a kaolinite-rich subsoil; in Germany only as relics from old (mostly Tertiary) weathering

Stauwasserböden: soils having a bleached topsoil or bleached aggregate surfaces and an Fe oxide accumulation in the interiors of the aggregates (if aggregates are present) due to redox processes caused by temporal water stagnation

Reduktosole: soils having a redistribution of Fe oxides due to redox processes caused by reducing gases like CO_2 or CH_4 (which maybe natural or anthropogenic)

Terrestrische Anthropogene Böden: soils having been changed by human activity (like deep cultivation or transportation of natural soil material) to such an extent that the natural horizon sequence is no longer present

Order Semiterrestrial Soils

Auenböden: soils originating from alluvial sediments that are periodically or episodically flooded and that have groundwater fluctuations over greater depth ranges

Gleye: soils having bleached horizons with Fe oxide accumulations on aggregate surfaces (if aggregates are present) or at root channels due to redox processes caused by groundwater that at least temporally reaches a depth above 40 cm below the mineral soil surface

Marschen: soils originating from tidal sediments and having groundwater influence

Strandböden: soils originating from sandy tidal sediments that are periodically or episodically flooded and show an initial accumulation of organic matter

Order Semisubhydric and Subhydric Soils

Semisubhydrische Böden: soils affected by regular tidal fluctuation

Subhydrische Böden: underwater soils covered by water not exceeding 2 m

Order Fens and Bogs

Naturnahe Moore: natural or only slightly altered fens and bogs

Erd- und Mulmmoore: drained and used fens and bogs showing (especially structural) changes toward a terrestrial soil formation

32.10 Classification Systems of Brazil, Canada, England and Wales, New Zealand, and South Africa

32.10.1 Introduction

The soil classification systems of Brazil, Canada, England and Wales, New Zealand, and South Africa have in common that they are developed in one, or at the most, two major world ecological regions, and therefore, focus on the characteristics important in that particular region. The Brazilian soil classification specializes in tropical soils, the Canadian system of soil classification focuses mainly on soils of the (sub)arctic and drier boreal regions, that of England and Wales aims at classifying soil conditions characteristic of the humid temperate regions, as does that of New Zealand, but with focus on volcanic regions, while the South African system is designed to classify soils in dry subtropical areas with emphasis on land use and management aspects.

32.10.2 The Brazilian System

Work on soil inventory of Brazil started in 1947 (Jacomine and Camargo, 1996). However, detailed descriptions and building of classification system started after 1964. The construction started "from top to bottom," filling the taxa with empirical content and developing lower taxonomic levels. Since the 1960s, the classification has gradually improved and became more descriptive and detailed (Jacomine and Camargo, 1996). The latest available version was published in 1999 (EMBRAPA, 1999). The structure and some diagnostic elements are very similar to the U.S. *Soil Taxonomy* (Soil Survey Staff, 1996); however, moisture and temperature regimes are not included as diagnostic criteria in the upper levels of the Brazilian taxonomy. The nomenclature, especially the names of higher categories, is closer to that of the WRB (IUSS Working Group WRB, 2006).

Brazilian soils are divided into 14 orders, at the first level. There are 150 great groups divided into 580 subgroups, which are defined according to qualitative variations in soil properties. The orders are defined as follows:

Alissolos: soils with evident active clay-enriched B horizon with high concentration of exchangeable aluminum

Argissolos: soils with B horizon enriched with low-activity (kaolinitic) clay

Cambissolos: soils with moderate alteration of the structure or color of the B horizon

Chernossolos: soils with dark humus-enriched topsoil horizon

Espodossolos: soils having evidences of iron and aluminum migration in organic complexes

Gleissollos: excessively humid soils affected with high groundwater level

Latossolos: deeply weathered soils

Luvissolos: soils with evident active clay-enriched B horizon with high base saturation

Neossolos: soils with moderate development

Nitososolos: deeply weathered clayey soils with well-developed aggregates with shiny surfaces

Organossolos: soils formed in organic parent material (peat)

Planossolos: soils with clay-depleted topsoil, where water stagnation causes prolonged reductive conditions

Plintossolos: soils having a discrete or continuous layer cemented with iron (hydr)oxides, formed by alternating reductive and oxidative conditions around the groundwater limit

Vertissolos: clayey soils with predominantly swelling clays, which expand in humid periods and shrink in dry seasons

32.10.3 The Canadian System

The Canadian system (Canada Soil Survey Committee, Subcommittee on Soil Classification, 1978) comprises a number of taxa, which are defined on the basis of soil properties; however, the system is genetically biased with respect to the definition of the higher categories. The system is differentiated as follows: orders, suborders, great groups, subgroups, families, and series. The following nine orders are recognized as follows:

Brunosolic: weak to moderately developed soils

Chernozemic: soils with a dark-colored, high base-saturated (dominantly Ca) A horizon, which is at least 10 cm thick and which have an organic carbon content between 1% and 17% (depending on clay content)

Cryosolic: soils that have permafrost within 1 m of the surface, or 2 m if they are strongly cryoturbated

Gleysolic: soils permanently or temporarily saturated with water and which experience reducing conditions

Luvisolic: soils with a subsurface horizon showing evidence of clay accumulation

Organic: soils dominated by organic horizons (horizons >17% organic C)

Podzolic: soils having a podzolic B horizon (horizon with accumulation of amorphous materials)

Regosolic: soils showing little or no soil development

Solonetzic: soils having a solonetzic B horizon (subsurface horizon with prismatic or columnar structures and a Ca/Na ratio ≥ 10)

32.10.4 The Soil Classification System of England and Wales

The differentiating criteria, which build the soil classification for England and Wales (Avery, 1980), comprise the composition of the soil material, the presence or absence of particular horizons or sequences of horizons, or other specified differentiating criteria. Ten MSGs are recognized, which are further subdivided in soil groups and soil subgroups. The 10 MSGs are as follows:

Brown soils: soils having a weathered (cambic) or argillic B horizon

Groundwater gley soils: soils influenced by the presence of a shallow fluctuating groundwater table

Lithomorphic soils: shallow soils (mineral substratum starting within 40 cm depth) with a distinct, humose, or peaty topsoil

Manmade soils: soils having a thick manmade A horizon or which are profoundly disturbed to depths exceeding 40 cm

Peat soils: soils with >40 cm organic material, or >30 cm if directly overlying bedrock, and lacking overlying non-humose mineral horizons extending below 30 cm

Pelosols: slowly permeable clayey soils

Podzolic soils: soils having a podzolic B horizon (subsurface horizon with accumulations of organic matter and Al, Fe, or both)

Raw gley soils: soils with a gleyed subsurface horizon lacking a distinct topsoil

Surface-water gley soils: soils having a gleyed subsurface horizon, which can be attributed to saturation by surface water

Terrestrial raw soils: soils consisting of little altered mineral material having no diagnostic surface or subsurface horizons

32.10.5 The New Zealand System

The newly published New Zealand soil classification (Hewitt, 1998) comprises 15 orders, which are subdivided into groups and subgroups. They are distinguished from each other by the presence or absence of diagnostic horizons and other differentia, some of which are unique to New Zealand. An important element in the classification is a listing of accessory properties of the order, some of which are directly related to soil management and conservation. The 15 orders are as follows:

Allophanic soils: soils strongly influenced by minerals with short-range order (especially, allophane, imogolite, and ferrihydrite)

Anthropic soils: soils formed by the direct action of people

Brown soils: soils having a weathered B, argillic, or cutanic horizon (horizon containing translocated material, which, however, fails to meet the requirements for argillic or Bh horizon), generally having a low base status

Gley soils: poorly and very poorly drained soils

Granular soils: clayey soils dominated by kaolinite-group minerals

Melanic soils: soils with highly base-saturated, well-structured, very dark A horizons

Organic soils: soils occurring in partly decomposed remains of wetland plants or forest litter

Oxidic soils: soils containing low-activity clays and secondary oxides, which give rise to variable charge properties

Pallic soils: soils with moderate to high base status and low contents of secondary Fe oxides

Podzols: acid soils with low base saturation and subsurface accumulation of organo-Al complexes, with or without Fe

Pumice soils: soils having properties dominated by a pumiceous and glassy skeleton with a low content of clay

Raw soils: soils lacking distinct topsoil development

Recent soils: soils showing only incipient marks of soil-forming processes

Semiarid soils: soils having a high base status and soil water deficit during the growing season

Ultic soils: acid soils with clayey and/or organic illuvial features

32.10.6 The South African System

The South African taxonomic system of soil classification (Soil Classification Working Group, 1991) comprises only two categories, soil forms and soil families. Soil forms are defined by a unique vertical sequence of diagnostic horizons and materials, while the soil families are separated on the basis of other properties. Nomenclature is South African in the sense that both soil forms and soil families bear local, geographical names (e.g., Escourt form, Haarlem family). So far, 73 soil forms are defined, divided into 406 soil families. The definitions of the diagnostic horizons and materials fit the unique South African conditions and are very difficult to correlate with other existing classification systems. Important elements for classification of the soil forms are the various topsoil horizons (organic O, humic A, vertic A, melanic A, and orthic A horizons), the pedality (apedal, structural grade weaker than moderate, vs. structured B horizons), various clay-enriched horizons (prismacutanic, pedocutanic, lithocutanic, and neocutanic B horizons), signs of wetness (e.g., soft and hard plinthic B horizons), carbonate accumulation (neocarbonate B horizon, soft carbonate horizon, and hardpan carbonate horizon), and nature of the underlying material (regic sand, stratified alluvium, saprolite, hard rock). Distinguishing criteria at soil family level comprise the thickness, colors, base status structure, consistency, and wetness of horizons.

33.1 Introduction: General Characteristics of Soil Orders and Global Distributions

Larry P. Wilding

Larry T. West

The purpose of this chapter is to present a discussion of the distribution, attributes, pedogenesis, classification, use, and management of the 12 soil orders recognized by *Soil Taxonomy* (Soil Survey Staff, "1999"). In this chapter, soil orders have been arrayed in a sequence to consider the organic soils first, followed next by soils that are weakly expressed or lack subsoil diagnostic horizons, and closing with soils exhibiting the greatest evidence of pedogenic weathering and/or accumulation of sesquioxides and translocated phyllosilicates. Only general statements can be made at this categorical level, but the information content becomes more precise as one descends to lower taxa (Sections 33.2 through 33.13). Because *Soil Taxonomy* is a dynamic classification system, the content is subject to change. For example, the most recent edition of the *Keys to Soil Taxonomy* (Soil Survey Staff, 2010) includes newly defined taxa for subaqueous soils (soils permanently inundated by shallow water) in the Histosols and Entisols (Sections 33.2 and 33.4).

Because of space limitations, data sets verifying the physical, chemical, mineralogical, and biological attributes of given orders are abridged. However, access to complete soil characterization databases, engineering properties, pedon descriptions, soil interpretations, and other information for different soil taxa are available online at the following address: http://soils.usda.gov/. For example, analytical data for more than 27,000 pedons in the United States and 1,100 pedons from other countries can

be accessed from this Web site. Standard morphological pedon descriptions are also available in most cases. Further, this Web site includes databases with listings of published soil surveys in the United States, Puerto Rico, Virgin Islands, Trust Territories, and some foreign countries; areal extent and classification of soil series; descriptions of ongoing soil survey investigations; various documents that define the standards used for soil surveys in the United States including field and laboratory methods; and links to Web Soil Survey and other soil surveys available in digital format.

The global distribution of soil orders at 1:1 million scale is illustrated in Figure 33.1—while Table 33.1 provides the areal extent of suborders associated with these orders. Tables 33.2 and 33.3 present proportional percentages of soil orders occurring in different soil temperature (Table 33.2) and soil moisture (Table 33.3) regimes as defined in *Soil Taxonomy* (Soil Survey Staff, 1999). Broad geographical distribution patterns (Figure 33.1) reflect regional conditions of climate, vegetation, geology, and topography, which function interactively over time. Soils found at any point on the land surface are considered products of multiple sets of pedogenic processes with state factors serving as controls (Chapter 30). Generally, soils are developed along polygenetic pathways, on dynamically evolving landforms under the influence of paleoclimates, in nonuniform parent materials. Hence, rarely can bio-, litho-, climo-, chrono-, and topo-sequence functions be developed with scientific rigor. Clearly, the distribution of soil orders in which local conditions strongly govern pedogenic dynamics over short-range distances is not well illustrated in Figure 33.1. In particular, such comments are germane to distributions of Histosols, Spodosols, Vertisols, and Gelisols. In these cases, the distributions presented in sections of this chapter may differ somewhat from those presented herein (Figure 33.1). This uncertainty will also impact the accuracy of

Global soil regions

global distributions and areal data given for Histosols, Andisols, and Inceptisols found interspersed with Gelisols.

The human impact on soils is recognized in some taxa of Entisols and Inceptisols, but, in general, *Soil Taxonomy* does not adequately handle the anthropogenic effects on soils. For example, Mollisols can be transformed into Alfisols when subject to severe erosion; paddy soils can undergo secondary salinization and waterlogging under long-term rice culture; soils in urban/ industrial environments can be markedly modified by landfills,

TABLE 33.2 Extent of Soil Orders Found in Different Temperature Regions

| Soil Order | Soil Temperature Regions[a] | | | |
	Tropical	Temperate	Boreal	Tundra

[a] Derived from soil temperature regimes defined in *Keys to Soil Taxonomy* (Soil Survey Staff, 2010).

Tropical: isomesic, isothermic, and isohyperthermic (MAST ≥ 8°C in which the difference in mean summer and mean winter soil temperatures is <6°C at 50 cm depth).

Temperate: mesic, termic, and hyperthermic (MAST ≥ 8°C at 50 cm depth).
Boreal: frigid, isofrigid, and cryic (MAST is 0°C–8°C at 50 cm depth).
Tundra: Gelic (MAST <0°C or <1°C in Gelisols).

TABLE 33.3 Extent of Soil Orders Found in Different Soil Moisture Regimes

| Soil Order | Soil Moisture Regimes[a] | | | |
	Aridic	Xeric	Ustic	Udic[b]
Alfisols	0	8	56	36
Andisols	4	3	30	63
Aridisols	95	1	3	1
Entisols	60	4	22	14
Gelisols	N/A[c]	N/A	N/A	N/A
Histosols	8	1	23	68
Inceptisols	0	6	42	52
Mollisols	0	13	66[d]	22
Oxisols	<1	0	35	65
Spodosols	<1	1	9	90
Ultisols	0	<1	42	58
Vertisols	28	3	56	13

[a] Soil moisture regimes defined in *Keys to Soil Taxonomy* (Soil Survey Staff, 2010).

[b] Udic soil moisture regime includes perudic moisture regime and soils with aquic conditions at a shallow depth (soil horizons saturated, reduced, and with redoximorphic features).

[c] N/A—not appropriate for the Gelisol order.

[d] A small percentage of Mollisols in the Ustic moisture regime may in fact have an Aridic soil moisture regime, especially in steppe regions of Eurasia that lie along the border between Ustic and Aridic soil moisture regimes.

landfarming, earth movement, and heavy metal contamination; and drastically, disturbed soils are common in regions where precious metals, rock aggregate, and fossil fuels have been mined. The International Committee on Anthropic Soils (ICOMANTH) where ANTH stands for anthropogenic is currently addressing this matter. For information on this activity, refer to the ICOMANTH Web site, http://clic.cses.vt.edu/icomanth/

Soil Taxonomy currently does not accommodate systematic cataloging of paleosols formed under remarkably different paleoenvironments. With increasing geomorphic age, properties of soils commonly reflect a welding of contemporaneous and paleoenvironments. In particular, when paleosols are well preserved, they are valuable proxies for biological and physicochemical evolution of the Earth. This is an area for *Soil Taxonomy* development that will likely gain greater attention in the future. With multiple uses of soil surveys for connectivity between the land surface and geological substrata (e.g., for environmental, hydrological, archaeological, and biogeoscience synergisms), there are increasing driving forces to observe soils beyond the 2 m depth limit currently in vogue. This is likely to enhance interest in revising *Soil Taxonomy* to better accommodate recognition and cataloging of paleosols as important morphogenetic markers of paleoenvironments (Chapter 29).

In perusing the global distributions of soil orders (Figure 33.1) and aerial extents given in Tables 33.1 through 33.3, several noteworthy relationships become apparent. These are summarized in a cursory overview in the following paragraphs. The organic-rich soils [Histosols (Section 33.2)], which comprises about 1.2% of the Earth's ice-free land surface (Table 33.1), generally occur in cool, humid, high latitude, boreal regions or in microhabitats such as seasonally ponded areas that favor the balance of organic matter accumulation over decomposition (Tables 33.2 and 33.3). This is because of saturated and reduced conditions, biological inhibitors, and/or cool, short summer periods with low evapotranspiration rates. Histosols are important wildlife and wetland habitats. Because they contain a disproportionally high level of soil carbon in relation to their aerial extent, Histosols are an important component of the global C cycle. These soils can be important sources of methane in the atmosphere, and accelerated organic matter decomposition resulting from more frequent drought and/or elevated temperatures associated with climate change not only potentially reduces their global abundance but also makes them a potential source of atmospheric carbon dioxide. Histosols are used extensively for cranberry, citrus, vegetable, rice, and sugarcane production and are a major fuel source in many regions. Major constraints to their use are subsidence, nutrient deficiencies, and wind erosion. Effective water-table management is critical in minimizing subsidence. These land resources are also critically limiting to construction activities because of their low soil strength and load bearing capacities.

Entisols (Section 33.4) comprise about 17.9% of the Earth's ice-free land surface (Figure 33.1). Over two-thirds of the Entisols are in the temperate region while the remainder mostly occur in the tropics (Table 33.2). Sixty percent of the Entisols

have aridic soil moisture regimes with ustic and udic being the next most extensive (Table 33.3). These are mineral soils, which do not have expression of diagnostic subsurface horizons within a specified depth of the soil surface, generally 1–2 m. Subsoil materials of these soils reflect the nature of the geological materials from which they were derived. These weakly expressed soils are commonly found on geomorphic surfaces, which are unstable because of frequent flooding, erosion/truncation, or human impact (drastically disturbed lands). They are formed also in coarse-textured, resistant mineral parent materials (e.g., quartzose sands) that are subject to little pedogenic development over time. Entisols are common along flood plains of river and stream valley systems, sand dunes in desert regions, on high-gradient mountainous terrain, and associated with recently mined or disturbed lands.

Andisols (Section 33.3) comprise <0.7% of the Earth's ice-free land surface (Table 33.1), but these soils are so unique physically, chemically, and mineralogically that a separate soil order was established for them. They are found along the tectonically active Pacific Ring of Fire, Central Atlantic Ridge, North Atlantic rift, the Caribbean, and the Mediterranean regions where volcanic or pyroclastic deposits are common (Figure 33.1). About half of them are located in tropical regions with the remainder split between temperate and boreal climates (Table 33.2). About two-thirds occur under udic soil moisture regimes and one-third in ustic regions (Table 33.3). These weakly developed soils are texturally undifferentiated and characterized by short-range order (amorphous) aluminosilicates that have not been translocated from upper to lower horizons. Andisol land resources are used extensively for crop production in developing countries. They commonly have favorable physical properties for plant growth while in many areas, high native fertility is present because of frequent additions of tephra that renew soil nutrients.

Inceptisols (Section 33.5), which comprise about 15.1% of the Earth's ice-free land surface (Figure 33.1), occur indiscriminately on a global basis because they lack a sharply defined central concept. Over 90% occur in tropical and temperate climates (Table 33.2) under ustic and udic soil moisture regimes (Table 33.3). Inceptisols serve to make *Soil Taxonomy* fully bifurcated. Soils classified as Inceptisols generally contain light-colored surface horizons with weakly expressed diagnostic subsoil horizons (cambic) but, under certain circumstances, may contain more strongly developed subsoil diagnostic horizons (e.g., petrocalcic, petrogypsic, duripan, and fragipan). Where these soils reflect youthfulness, they occur in high-gradient mountainous regions, along major river systems as terraces and deltaic/fluvial plains, and as soils developed from carbonate-rich bedrocks or sediments in Mediterranean environments. They also occur interspersed among more strongly developed Alfisols, Ultisols, and Oxisols in tropical and subtropical regions. Properties of Inceptisols vary widely as does their potential for plant production and engineering use.

Gelisols, the newest of the soil orders (Section 33.6), comprise about 9.0% of the Earth's ice-free land surface (Figure 33.1). These are soils of the high-latitude polar regions underlain by permafrost (materials wet/dry that remain below 0°C for 2 consecutive years) at depths of 1–2 m depending on cryoturbation (frost churning) activity (Table 33.2). Cryoturbation in Gelisols is driven by the physical volume change from water to ice and subsequent moisture migration along thermal, hydrostatic, chemical, and electrical gradients. Cryopedogenic processes include freezing/thawing, cryoturbation, frost heaving, cryogenic sorting, thermal cracking, and ice segregation. Remarkable spatial variability occurs in soil properties over distances of a few meters or less giving rise to pattern ground in the form of stone stripes, stone circles, high and low center polygons, and barren frost boils. Because Gelisols are large C sinks, warming in polar regions may result in melting of permafrost, increased organic matter decomposition, and increased CO_2 release to the atmosphere. Gelisols present management challenges because of volume changes associated with cryopedogenic processes. In addition, melting of ice following disturbance associated with construction or agricultural production leads to subsidence or thermokarst. Only through careful management of subsurface ice and maintenance of a negative thermal balance can the integrity of structures be preserved.

Vertisols (Section 33.7) comprise about 2.4% of the Earth's ice-free land surface (Figure 33.1). About half the Vertisols are found in tropical and about half in temperate environments (Table 33.2). Over 50% of the Vertisols occur in regions with ustic soil moisture regimes where seasonal desiccation is common. The remainder are found primarily under aridic and xeric environments; here, the oscillation from wet to dry soil conditions is less frequent (Table 33.3) and gilgai expression less extreme. These clayey, shrink/swell soils are highly diverse in physical, chemical, biological, and mineralogical properties. Although concentrated in subtropical and tropical environments, they do occur across broad climatic, vegetative, topographic, and geologic regions of Africa, India, Australia, China, and North and South America (Figure 33.1). Swelling caused by wetting dry Vertisols often results in soil failure when swelling pressures exceed shear strength. Soil failure is usually expressed as slickensides occurring as diagonal, polished, and grooved slip surfaces, wedge-shaped structural units, and microtopography in the form of gilgai. Commonly, these soils have self-swallowing and self-mulching surface features where strongly aggregated surface materials fill in vertical structural cracks. While inversion by turbation is commonly invoked as a major pedogenic processes, most movement in these soils is believed to be diagonally along inclined major slickenside fault planes. Major limitations for using these highly productive soils for agriculture, especially in developing countries, are their high energy requirements for tillage and narrow favorable soil moisture range for workability. Construction activities are constrained by their propensity for soil failure and high shrink/swell activity.

Mollisols (Section 33.8) comprise about 7% of Earth's ice-free land surface (Figure 33.1). Essentially, all the Mollisols are approximately equally split between temperate and boreal regions (Table 33.2). About two-thirds of the Mollisols are in

ustic soil moisture regimes (Ustolls) with most of the remainder occurring in regions with a udic moisture regime (Udolls) and the rest in climates with winter precipitation and summer periods of soil moisture deficit (Xerolls) (Table 33.3). A few Mollisols may occur under aridic soil moisture regimes in the southern steppe zones of Eurasia but their extent is uncertain. Mollisols are the dark-colored, high base status soils commonly found under prairie grass vegetation in mid-latitudes of North and South America and Eurasia. The distribution pattern of these soils in Eurasia is in east-west trending belts between Alfisols to the north and Aridisols and Inceptisols to the south. This distribution reflects decreasing precipitation and increasing temperature gradients from north to south. In contrast, in North America, the precipitation isohyets and isotherms are set normal to each other with precipitation decreasing from east to west and temperature increasing from north to south. These climatic controls result in Mollisols being bordered on the east by Alfisols and Ultisols, and to the west by Aridisols, Entisols, and drier Alfisols. Mollisols are commonly associated with calcareous or high base status glacial drift, limestones, and loess. Mollisols (especially Udolls) are the "bread basket" soils of the Americas and Eurasia because their high native fertility, occurrence in favorable climates, and excellent physical and chemical properties result in high crop production potentials.

Spodosols (Section 33.9) comprise about 3.5% of Earth's ice-free land area (Figure 33.1) with over 80% occurring in boreal environments (Table 33.2) with udic soil moisture regimes (Table 33.3) between Mollisols of mid-to-high latitudes and Alfisols in lower latitudes. Spodosols are also commonly associated with imperfectly drained sediments in coastal regions such as the Atlantic Coast of the southeast United States. Spodosols commonly have prominent eluvial E horizons overlying black to red spodic and placic horizons. The spodic horizons have formed from translocated illuvial organo-metal (Al and Fe) complexes. These soils have many properties in common with Andisols. The major difference is that Spodosols have formed for a sufficient period of time for the weathered organic–metal complexes to be translocated to subsoils. In Andisols, little or no translocation of these complexes has taken place. Formation of Spodosols is favored by environments with abundant acid litter, coarse-textured resistant parent materials, and strong leaching potentials. These soils are very strongly acid and extremely phosphorus deficient. Native vegetation is composed largely of acid tolerant plants. They are little used for agricultural production because of low nutrient and water retention and high management requirements. The major land use is forests for lumbering and recreation.

Aridisols (Section 33.10) which comprise about 11.9% of the Earth's ice-free land area (Figure 33.1) occur mostly in hot temperate deserts with aridic soil moisture regimes, dry coastal regions, or on rain-shadow plains leeward of high mountains (Tables 33.2 and 33.3). Locally, they also occur in more humid regions where salts have concentrated at or near the soil surface through evaporative pumping from shallow saline ground waters. Aridisols range from base-rich to base-poor soils and exhibit a wide diversity in physical, chemical, and mineralogical properties. Commonly, they represent contemporaneous xerophytic environments, but some Aridisols have well-expressed subsoil diagnostic properties such as argillic, natric, calcic, petrocalcic horizons. These likely reflect more pluvial paleoclimates, and the diagnostic horizons would be, in part, relict. Aridisols are used extensively for rangelands, military bases, and nomadic agrarian activities. Although these soils are not generally considered arable land resources without irrigation, where an adequate quantity of high-quality subsurface water is available they become suitable for intensive agriculture and urban development. Irrigation and drainage must be managed for a favorable salt balance in Aridisols.

Alfisols (Section 33.11) and Ultisols (Section 33.12) are closely related soil orders that comprise, respectively, about 10.1% and 8.1% of the Earth's ice-free land area (Figure 33.1). These soils, developed mostly under deciduous forested or savannah environments, occur extensively in mid-to-lower latitudes. Alfisols are distributed approximately equally across tropical, temperate, and boreal environments whereas the distribution of Ultisols is skewed toward tropical conditions (Table 33.2). For both Alfisols and Ultisols, most of their extent is associated with ustic and udic soil moisture regimes (Table 33.3). Alfisols and Ultisols are differentiated from other orders on the basis of textural differentiation between surface and subsoil horizons. The textural differentiation partly defines argillic and kandic horizons and has often resulted from translocation and/or in situ neoformation of clays. Alfisols differ from Ultisols in having higher base saturation (>35%) at a specified depth in the subsoil. Rationale for this differentiation was that Alfisols could sustain traditional slash/burn subsistence agriculture without significant external fertilizer inputs, while Ultisols would require applied nutrients for crop production. Both orders are used extensively for forest and crop production. Major limitations are nutrient deficiencies, wind and water erosivity, and seasonal soil moisture deficits, especially for those in xeric and ustic regions.

Sesquioxide-rich Oxisols (Section 33.13) comprise about 7.6% of the Earth's ice-free land surface occurring in equatorial regions intermixed with Ultisols and Inceptisols (Figure 33.1). Nearly all the Oxisols occur in tropical environments (Table 33.2) with two-thirds under udic and one-third under ustic soil moisture regimes (Table 33.3). Oxisols contain low activity clays and are nutrient poor, weakly buffered systems that have little or no horizon differentiation. This reflects (1) their high weathering intensities in low latitude, humid environments, (2) their geomorphic stability and age associated with mafic-rich, Precambrian platforms, or (3) development from polcycled, pre-weathered parent materials derived from highly weathered terrestrial source areas. These soils are often considered residual carcasses, but many are very productive for agriculture and forestry if properly managed for water conservation, soil erosion, and nutrient inputs. With high nutrient inputs and management to conserve soil and water, Oxisols can be very productive agricultural soil systems.

33.2.1 Introduction

While most soils of the world comprise primarily mineral materials, a small but important group of soils are formed from organic materials derived from plants, or less frequently, from animals. *Organic soil materials* contain a minimum of 12%–18% organic carbon, depending on the particle size of the mineral component (Soil Survey Staff, 2010). Generally speaking, soils with at least 40 cm of the upper 80 cm that are organic materials, and which do not have permafrost within 1 m of the soil surface, are Histosols. Prior to 1997, organic soils with permafrost were included in the Histosol order; they are now placed in the Histel suborder of Gelisols (Soil Survey Staff, 1998). Following the separation of Histosols and permafrost soils, Histosols occupy about 1% of the global land area while the Histel suborder of Gelisols occupies about 0.8% (Buol et al., 2003). Organic soil materials are commonly referred to as *peat*, and land covered by Histosols or Histels is known as *peatland*. The term *mire* is a synonym of peatland that is more commonly used in Europe. Histosols also include a narrowly distributed group of soils, the Folists, that consist of well-drained organic soil materials that directly overly bedrock or coarse fragments with little or no intervening fine soil. The peat layer in Folists may be (and usually is) thinner than the 40 cm required for other Histosols.

Because of their high organic C content, many Histosols have been utilized as a combustible energy resource. Mankind has mined and burned peat since prehistoric times, and peat is still an important fuel in a number of northern countries, although it has a lower energy rating than oil or coal. In Russia, Germany, and Ireland, peat is not only utilized for domestic heating but is also used on a large scale in electricity generation. In 2009, peat burning was the source of 10% of Ireland's electricity (Public communication, 2009a), and in 2003, about 7% of Finland's electricity was a result of burning peat (Kirkinen et al., 2007). Sweden, Belarus, Latvia, Estonia, and Lithuania also utilize peat for energy; and Canada is currently investigating the possibility of using peat for power production in Ontario and Labrador (Public communication, 2009b, 2009c). In addition to being mined as an energy source, peat is mined for use as a soil amendment in agriculture and horticulture. Moreover, the agricultural value of Histosols has long been recognized. Provided that the water tables can be effectively managed, high yields of vegetables and other specialty crops can be produced on Histosols in such different climatic regions as Michigan and Florida (Lucas, 1982).

Because most Histosols occur in wetlands,* their utilization as agricultural and energy resources has come under intense scrutiny. Histosols perform many of the beneficial functions of wetlands, and they are negatively impacted by mining, drainage, or other practices associated with agriculture; thus, there are benefits derived from preservation of Histosols in their natural state. Histosols are perhaps uniquely fragile and are highly vulnerable to degradation. When drained or dry, organic soil material is highly susceptible to wind and water erosion (Lucas, 1982; Parent et al., 1982). Organic soils also have very low strength, are highly compressible (MacFarlane, 1969; MacFarlane and Williams, 1974), and gradually subside by decomposition if drained (Gesch et al., 2007). Furthermore, within the framework of current discussions of global climate change and carbon budgeting, Histosols contribute significantly to the terrestrial carbon pool. On an areal basis, C storage in Histosols is often greater than mineral soils by an order of magnitude (Rabenhorst, 1995).

33.2.2 Distribution

Histosols occur at all latitudes, but are most prevalent in the boreal forest regions of northern North America, Europe, and Asia (Figure 33.2). The world's largest expanses of Histosols occur in the West Siberian lowland (Walter, 1977) and the Hudson Bay lowland of central Canada (Sjors, 1963; Canada Committee on Ecological (Biophysical) Land Classification, National Wetlands Working Group, 1988). At lower latitudes, Histosols occur locally on humid coastal plains, notably southeast Asia and Indonesia (Anderson, 1983).

Histosols in the United States are most widespread in lowlands of the Great Lakes region, the northeast, the Atlantic Coastal plain and Florida, the Pacific Northwest, and Alaska (Figure 33.2). The largest expanses of Histosols in the continental United States are on the Lake Agassiz plain in north-central Minnesota (Wright et al., 1992). Coastal and estuarine areas inundated by tidal water are also sites for Histosol formation, most notably along the Atlantic and Gulf coastlines. Drained Histosols are widely used in agriculture in the Great Lakes region, southern Florida, and the Sacramento–San Joaquin delta region of California. In the semiarid Great Plains and mountainous west, Histosols are very rare and occur only in areas of steady groundwater discharge (Mausbach and Richardson, 1994) or humid areas at high elevations (Cooper and Andrus, 1994). Organic soils are widespread in lowlands throughout Alaska, although most of the organic soils in central and northern Alaska have permafrost and hence are classified as Histels in the Gelisol soil order rather than Histosols.

---

* The National Technical Committee on Hydric Soils (USA) has included "All Histosols except Folists" within the criteria for hydric soils (USDA-NRCS, 1996).

33.2.3 Formation of Histosols

33.2.3.1 Parent Material

In contrast to the wide variety of mineral materials, which may serve as parent materials for other soils, the parent materials from which Histosols are formed are organic in nature. The conditions that cause the accumulation of organic parent materials are very closely tied to the processes, which form various organic soil horizons. The unique properties of Histosols result from the nature of the organic parent material.

Some of the factors, which affect the nature of organic parent materials, include hydroperiod, water chemistry, and vegetation type and will be discussed in more detail in the following sections. The net accumulation of organic materials occurs when rates of additions (usually as primary plant production) exceed rates of decomposition. In natural soils of most ecosystems, a steady state exists between these two processes, which maintains the quantity of organic C in the surface horizons somewhere between 0.5% and 10%, although some forest soils have relatively thin layers of organic soil materials (O horizons). In Histosols, the rates of decomposition are slowed and organic matter accumulates to the degree that the organic materials amass to a significant depth. In most cases, this is caused by saturation in soils leading to anaerobic conditions, which causes organic matter decomposition to be less efficient than under aerobic conditions. Occasionally, usually under cool and moist conditions, organic parent materials may accumulate without prolonged saturation, producing soils in the unique Folist suborder of Histosols. Under certain conditions and landscapes, mineral materials can be added to accumulating organic parent materials, typically by alluviation or eolian deposition. In such cases, the balance between mineral inputs and organic accumulation will determine whether a Histosol or mineral soil will form.

The accumulation of organic parent materials often occurs over long periods of time and under changing conditions.

Thus, the stratigraphy of a bog may reflect many thousands of years of organic matter accumulation. Rarely does vegetation remain constant over such long periods. Microscopic examination of the partially decomposed peat or evaluation of pollen or plant microfossils can provide information concerning the types of plants that have contributed to the organic parent material during various stages of accumulation (e.g., Wieder et al., 1994).

The organic parent material of Histosols is a major source of acidity. Acids produced by the partial decomposition of organic matter cause the organic horizons of Histosols to be highly acidic unless the acids are neutralized by bases that were dissolved from mineral soils or rocks and transported into the peat by groundwater. Highly acidic peatlands are called *bogs* and commonly described as *ombrotrophic* (rain-fed, because all nutrients are derived from atmospheric sources). The less acid Histosols that receive base-rich groundwater or runoff are called *fens* and usually described as *minerotrophic* (fed with mineral-derived nutrients). The term *swamp* is often applied to forested systems on both fens and on mineral soil wetlands. Peatlands are also sometimes divided by their acidity into *oligotrophic* (very acid and mineral-poor), *mesotrophic* (intermediate), and *eutrophic* (weakly acidic to neutral and mineral-rich) classes (Moore and Bellamy, 1974; Gore, 1983).

33.2.3.2 Climate

Histosol formation is favored by wet or cold climates. Wetness and cold favor Histosol formation by hindering decomposition of organic matter. The northern Histosol-dominated regions of North America and Eurasia (Figure 33.2) have temperate and boreal climates in which average annual precipitation exceeds annual potential evapotranspiration (Trewartha, 1968). Further to the north, in Greenland and the islands bordering the Arctic Ocean, for example, Histosols are rare because the growing season is so short that there is little production of organic matter. To the south of the boreal zone, Histosol formation is apparently

constrained by rapid decomposition of soil organic matter. At lower latitudes, Histosols are restricted mostly to coastal plains with very flat topography, high annual precipitation, and no dry season, or to those areas where a high water table is maintained by tidal waters, leading to coastal marshes and mangrove systems (Anderson, 1983).

Climate affects not only where Histosols occur, but also the chemistry of the resulting soils. Where average annual precipitation exceeds annual potential evapotranspiration, Histosols in suitable settings can remain saturated by rainfall alone (Ivanov, 1981). In such regions, both the highly acidic Histosols of bogs and the less acid Histosols of groundwater-fed fens may form. In less humid regions, where groundwater is required to maintain saturation of soils, only the less acid, minerotrophic Histosols can form.

Climate change scenarios suggest more frequent extreme events such as heat waves, droughts, and high precipitation events (IPCC, 2007). Increases in drought and heat will likely lead to a higher frequency of fire in the boreal zone resulting in significant losses of C from Histosols. Currently, disturbances, mainly fire, reduce the net C uptake of continental boreal peatlands by about 85% (Turetsky et al., 2002). Predicted increases in fire frequency and intensity could lead to an even greater proportion of C uptake being balanced by fire, and boreal peatlands may actually become a net C source to the atmosphere (Turetsky et al., 2002).

33.2.3.3 Topography

While climate controls the occurrence of Histosols on a regional scale, topography controls where they occur on a given landscape. The classical soil-forming factor of topography is considered broadly here to incorporate relief, geomorphic setting, and hydrologic setting. Histosols occur where the setting facilitates concentration of runoff, discharge of groundwater, or retention of precipitation (Figure 33.3a through c). These conditions are most often satisfied in topographic depressions or very flat areas. On plains with low-permeability substrates in the boreal zone, Histosols may cover entire interfluves (Sjors, 1963; Walter, 1977), and in extremely humid climates, such as the British Isles and southeastern Alaska, Histosols may also occur on gentle slopes (Moore and Bellamy, 1974; Sjors, 1985; Ward et al., 2007). Histosols of floodplains receive suspended mineral matter during floods, while other Histosols obtain only dissolved material from source waters or inputs of eolian materials.

In lower latitude coastal areas, rising sea level has caused brackish or saline waters to engulf drowned river valleys or to extend over formerly upland soils. This has led to the formation of coastal marsh Histosols in several geomorphic settings (Darmody and Foss, 1979). Figure 33.4 shows a schematic of a cross section of a submerged upland type marsh where organic soil materials are accumulating over what were previously upland soils, forming Histosols. As sea level continues to rise, the margin of the marsh is pushed landward, and the organic materials continue to thicken such that older and deeper Histosols generally exist closer to the open water (Rabenhorst, 1997).
FIGURE 33.3 Settings of peatlands. Peat is shown in gray, and arrows indicate the direction of water movement (a) Bog. The domed surface of the bog precludes input of runoff or groundwater containing bases dissolved from minerals. All water is derived from the atmosphere and evaporates or runs radially off the bog. (b) Fen or swamp. Runoff and groundwater from mineral soils surrounding the peatland supplement precipitation on the peatland. (c) Floodplain fen or swamp. The peatland receives precipitation and runoff or groundwater from mineral soils adjacent to the peatland. Water seeps from the peatland into the stream during periods of low water, while during floods suspended mineral matter is deposited on the peatland, increasing the content of mineral matter in the peat.
FIGURE 33.4 A schematized cross section of a submerged-upland type marsh showing development of O horizons and a Histosol (probably a Sulfihemist) over what was formerly an upland soil with an argillic (Bt) horizon.

The formation of Histosols, like other soils, is a function of topography, but Histosols are unique among soils in that their formation also modifies the topography. Accumulation of organic soil material can fill depressions and create gentle topographic highs where the topography was once level or depressional (Figure 33.5). The development of a topographic high due to peat accumulation can prevent base-rich water from moving onto the peatland and thereby facilitate formation of a highly
FIGURE 33.5 Stratigraphic cross section of a bog in the Myrtle Lake peatland, northern Minnesota. (Modified from Heinselman, M.L. 1970. Landscape evolution, peatland types and the environment in the Lake Agassiz Peatlands Natural Area, Minnesota. Ecol. Monogr. 40:235–261.)

FIGURE 33.6 Typical bog vegetation on a highly acidic Histosol in boreal North America. Trees are stunted black spruce (*Picea mariana*); the largest trees visible are about 4 m tall. Understory plants include ericaceous dwarf shrubs, sedges (*Carex* sp.), and a continuous cover of *Sphagnum* sp. moss. The soil is a Typic Borohemist. Toivola peatland, northeastern Minnesota.

acidic bog. Peat accumulation also produces intriguing microtopography on some peatlands, notably a pattern of ridges (or *strings*) and pools (Foster et al., 1983; Seppälä and Koutaniemi, 1985; Swanson and Grigal, 1988) (or *flarks*), the cause of which is still debated (Washburn, 1980).

Histosols frequently form by accumulation of organic matter in basins of lakes or ponds, a process known as *lakefill* or *terrestrialization*. Histosols may also form by *paludification*, the expansion of wetland onto what was originally drier soils. Both processes operated in the formation of the peatland depicted in Figure 33.5. Folists, unlike other Histosols, generally occur in mountainous regions (Reiger, 1983; Wakeley et al., 1996). Mountainous settings provide the high precipitation and underlying bedrock or fragmental material required for Folist formation.

33.2.3.4 Vegetation

The flora of Histosols varies widely as a result of the great range in climates over which they occur. Moreover, while most Histosols owe their existence to saturation of the soil by water, the depth at which saturation occurs is variable and this has a major effect on the vegetation. The vegetation of bogs in the worldwide circumboreal zone is remarkably uniform, apparently due to the limited number of plants that can tolerate the poor nutrient conditions, cold climate, and high water table of these soils (Figure 33.6). *Sphagnum* mosses cover the ground, along with scattered sedges (*Carex*) and cotton sedges (*Eriophorum*). Low shrubs from the family Ericaceae are common, and trees are usually present but stunted; black spruce (*Picea mariana*) is most widespread in North America and Scot's pine (*Pinus sylvestris*) in Eurasia. The vegetation of bogs in more southerly climates includes different species, but shares with northern bogs the *Sphagnum* moss and prevalence of nutrient-conserving evergreen plants (Anderson, 1983; Hofstetter, 1983).

The less-acid conditions of groundwater-fed Histosols permit a greater diversity of plants, many of which also occur on wet mineral soils. On minerotrophic peatlands with the water table continuously near the surface (fens), most vascular plants are *aerenchymous* grass-like plants (mainly sedges, family Cyperaceae) that can transport oxygen downward to their roots in hollow stems, allowing root metabolism in anaerobic soils (Crawford, 1983). Fens that exhibit an aerobic surface horizon present during at least part of the growing season, allow growth of nonaerenchymous plants, including woody plants (Gill, 1970; Kozlowski, 1984). Though nutrient conditions for tree growth on these Histosols are superior to those of bogs, trees may be stunted due to short duration of aerobic conditions or thinness of the aerobic rooting zone.

Many of the plants that occur on Histosols are highly adapted to specific conditions of pH/nutrients and high water table; thus, plants are useful indicators of these conditions (Heinselman, 1963, 1970; Sjors, 1963; Jeglum, 1971; Vitt and Slack, 1975; Vitt and Bayley, 1984; Andrus, 1986; Janssens and Glaser, 1986; Swanson and Grigal, 1989, 1991; Glaser, 1992; Janssens, 1992). Because the high water table restricts rooting of most plants to near-surface soil horizons, vegetation is a useful indicator of pH/nutrient conditions near the surface but not at depth.

Because the vegetation actually creates most of the soil material in Histosols, composition of the vegetation that formed the soil exerts strong control over its physical and chemical properties. Peats are commonly divided into three broad groups on the basis of botanical composition: moss, herbaceous (sedge), and woody peat (Kivinen, 1977). The botanical origin of organic soil material may be determined by examination of plant remains (Birks and Birks, 1980; Janssens, 1983; Levesque et al., 1988).

The changes in soil drainage and trophic conditions on peatlands that accompany peat accumulation affect the vegetation and hence botanical composition of the peat. As peat

accumulates, the rooting zone often becomes more and more isolated from mineral nutrient sources, and portions of the peatland may become drier as the ground surfaces rises. A cross section of a bog in Minnesota shows how a lake was filled in with aquatic peat (i.e., limnic material; Figure 33.4). Then, the peatland expanded onto what was originally dry land of the lakeshore as minerotrophic sedge peat was followed by minerotrophic forest peat as the surface rose and became drier. By about 3000 years ago, the center of the peatland became isolated from minerotrophic water, allowing accumulation of highly acidic *Sphagnum* moss peat, which subsequently expanded over the entire peatland and continues to accumulate today. Such changes in vegetation over time in peatlands make it difficult to predict subsurface peat properties from surface vegetation (Swanson and Grigal, 1989).

33.2.3.5 Time

Essentially all extant Histosols have formed since the end of the Pleistocene epoch. Most northern latitude Histosols occupy regions which were covered by glaciers during the last ice age and have formed following the glacial retreat. Reported average rates of peat accumulation in northern bogs and fens have been as high as >3 mm year^{-1}, but more typically fall in the range of 0.2–0.7 mm year^{-1} (Table 33.4). These average rates usually are based on basal ^{14}C dates, and actual rates may have been higher or lower during particular periods.

Although distant from the glacial activity, coastal Histosols at lower latitudes were also impacted by the glaciation. During the glacial maximum (approximately 20,000 years ago), sea level worldwide was approximately 150 m below the present level when large quantities of water were tied up in the glacial ice. Melting of the ice and concurrent ocean warming caused sea level to rise at such a rapid rate (10–20 mm year^{-1}) that initially vegetation could not colonize the tidal regions. Approximately 3000–5000 years ago, sea level rise slowed to a more modest pace such that marsh vegetation could become established and organic parent materials began to accumulate (Bloom and Stuvier, 1963; Redfield, 1972). As sea level has continued to rise, organic materials have accumulated in Histosols, and coastal marshes and mangrove systems generally have been thought to have accreted at approximately the rate of sea level rise.

In addition to the eustatic sea level rise, sediment in transgressing coastal regions is subsiding (e.g., along the Atlantic and Gulf coasts of the United States). The combination of rising sea level (presently estimated at 1 mm year^{-1} worldwide) and coastal subsidence can be joined to yield an apparent sea level rise, which is substantially greater. Estimates of peat accretion in coastal areas generally range from 3 to 8 mm year^{-1}, which are much higher than in noncoastal regions, with even higher rates reported in rapidly subsiding areas (Table 33.4). Current evidence suggests that the highest rates of sea level rise may be too great for marsh systems to maintain, and that some of these areas are suffering marsh loss (Kearney et al., 2002).

33.2.4 Morphological Properties of Histosols

Most organic soil material is derived from terrestrial plants, and soil particles initially resemble the plants from which they were derived. As decomposition progresses, the organic matter is converted into a homogenous, dark-colored mass. Some organic soil materials are derived from aquatic plants and animals that accumulate on the bottom of water bodies, producing *limnic materials* (Finney et al., 1974; Soil Survey Staff, 2010).

The most obvious morphological properties of organic soil horizons are related to their degree of decomposition. Master horizons Oi, Oe, and Oa are used to designate fibric, hemic, and sapric horizons, respectively (Table 33.5) and are defined by the portion of the soil material, which retains discernable plant fibers after rubbing and by the color of a Na pyrophosphate extracting solution (Soil Survey Staff, 2010). Other methodologies and rating scales have been developed and utilized for evaluating degree of decomposition; the one most broadly used in Europe is the Von Post scale, which ranks organic materials on a scale of decomposition from 1 to 10 based on soil color, quantity of recognizable fibers, and the proportion of material remaining in one's hand when the sample is squeezed. Von Post scale numbers 1–4 correspond approximately to fibric material, 5–7 to hemic, and 8–10 sapric (Von Post and Granlund, 1926; Clymo, 1983).

There are a number of soil properties which are related to the degree of decomposition of the organic materials, including color and a variety of physical and chemical properties. Field moist colors of sapric organic soil material are usually

TABLE 33.5   Defining Morphological Criteria for Histosol Organic Horizons

Horizon Designation	Type of Material	Common Descriptor	Volumetric Rubbed Fiber (RF) Content	Color of Pyrophosphate Extract (Value/Chroma)
Oi	Fibric	Peat	RF > 3/4 or RF > 2/5	7/1, 7/2, 8/1, 8/2, 8/3
Oe	Hemic	Mucky peat	2/5 > RF > 1/6	Does not otherwise qualify for either fibric or sapric materials
Oa	Sapric	Muck	RF < 1/6	Below or right of line drawn to exclude blocks 5/1, 6/2, 7/3

nearly black. Fibric peat is lighter colored and often reddish in hue, while hemic peat has an intermediate color (Table 33.6). The relation between the degree of decomposition and various physical properties is discussed later under the section on physical properties.

Undrained Histosols typically lack pedogenic structure as it is usually defined, although flattened plant remains and stratification commonly produces a plate-like structure (Lee and Manoch, 1974). This sedimentary structure often results in Histosols having different shear strength and hydraulic conductivity in horizontal and vertical directions (MacFarlane and Williams, 1974; Rycroft et al., 1975). Drained Histosols may develop pedogenic structure in the man-made aerobic zone, such as granular structure due to earthworm casts and blocks or prisms due to cycles of wetting and drying (Lee and Manoch, 1974).

The mineral soil material that occurs under the peat in Histosols is typically chemically reduced as a result of saturation by water and the abundance of organic matter above it. Where paludification has occurred, soil horizons of prior mineral soils may be buried beneath the peat. In some cases, the preceding mineral soil pedogenesis may facilitate paludification by producing low-permeability horizons such as placic horizons (Ugolini and Mann, 1979; Klinger, 1996). The depth to mineral soil underlying drained Histosols has been measured with some success by ground-penetrating radar (Shih and Doolittle, 1984; Collins et al., 1986; Sheng et al., 2004; Kettridge et al., 2008).

The morphology of Folists differs from that of other Histosols in that the peat layers are thinner and underlain by fragmental material or bedrock (Witty and Arnold, 1970; Everett, 1971; Lewis and Lavkulich, 1972). Folists drain freely and as a result are less saturated than other Histosols (not saturated for >30 cumulative days per year; Soil Survey Staff, 2010).

TABLE 33.6   Color of Organic Soil Material in Relation to Degree of Decomposition[a]

Degree of Decomposition	Median Munsell Color (Hue Value/Chroma)	N
Sapric	10 YR (2/1)	69
Hemic	10 YR (3/2)	49
Fibric	7.5 YR (3/2)	18

33.2.5 Micromorphology of Histosols

Micromorphological observations can provide a direct examination of the structural integrity of plant fragments and components in organic soil materials. Levesque and Dinel (1982) and Fox (1985) have summarized the characteristics of organic soil materials at various stages of decomposition (fibric, hemic, and sapric materials). Fibric materials mainly show unaltered or slightly altered plant tissues without appreciable darkening and with little organic fine material. The plant fragments, which are only slightly decomposed, appear to be loosely arranged with a porous and open structure. Partially decomposed (hemic) materials also possess a fibrous appearance, and most fragments show incomplete degradation. The development of brown or black colors in the plant tissues is typical. Fine organic material is also present intermixed with, or adhering to, the coarser fragments of plant tissue (Figure 33.7). Fecal pellets, which are evidence of faunal activity, can also be common. In the most highly decomposed (sapric) materials, organic fragments are sufficiently darkened and decomposed, so that identification of botanical origin is not possible. Fine organic material is usually the dominant component although faunal excrement is also common.

The effects of draining organic soils can sometimes be seen during microfabric examination. When an undrained sphagnum

FIGURE 33.7   Thin section showing organic material from hemic Oe horizon (80–88 cm) of a Typic Sulfihemist in a coastal marsh of Chesapeake Bay; the organic material reflects an intermediate degree of decomposition with some discernable plant structures and cell components intermixed with decomposed organic material; frame length = 5 mm; PPL.

peat profile in Ireland was compared with those which had been drained for between 10 and 100 years, the drained profiles had undergone substantial alteration and decomposition leaving little of the original tissue structures (Hammond and Collins, 1983). The fine organic material was dominant, showing some biological granulation (Pons, 1960; Lee, 1983). The change in microfabric materials directly corresponded to an increase in density of the material.

In another study, Lee and Manoch (1974) concluded that 50 years of drainage and cultivation of organic soils led to significant decomposition and the development of pedogenic structure in the subsoil, whereas in the lower portion of the profile where the soil remained saturated, sedimentary structure persisted and the peat was more highly fibrous and less decomposed. The activity of soil fauna in the drained portions of the soil contributed to biological granulation and the formation of two distinct types of surface horizons. The *moder* mostly consists of faunal excrement and usually forms in oligotrophic peats, while the *mull* is formed by an intense mixing and binding of organic with mineral particles by larger organisms such as earthworms, and usually forms in mesotrophic or eutrophic peats.

While not widely reported, following drainage and cultivation of organic soils, illuvial humus termed *humilluvic material* (Soil Survey Staff, 2011) may accumulate in the lower parts of acid organic soils (Van Heuveln et al., 1960). Both the lower pH of the oligotrophic peat and the disturbance by cultivation apparently contribute to the dispersion of the organic fraction, which can then be translocated within the soil, and accumulate within the lower horizons of the peat, at the peat–mineral soil contact, or within the underlying mineral soil material.

33.2.6 Classification of Histosols

The definition of *organic materials* for saturated soils requires a minimum of 12% OC if there is no clay, and a minimum of 18% OC if the soil contains 60% or more clay, with a sliding scale for intermediate textures. Those soils which are not saturated must contain at least 20% OC to be considered organic soil materials (Soil Survey Staff, 1998, 2011). For a soil to be classified as a Histosol, at least 40 cm of the upper 80 cm must comprise organic materials, and it must not have permafrost within 1 m of the surface. However, if the organic materials are especially low in density (<0.1 g cm⁻¹), then at least 60 cm of the upper 100 cm must be organic materials. Histosols may be buried by as much as 40 cm of overlying mineral soil materials and still be considered Histosols.

The types of differentiating characteristics used to discriminate between classes of soils at the various categorical levels are presented in Table 33.7. Basically, organic soils that are not saturated for extended periods are classified as Folists, while the saturated organic soils are differentiated according to the degree of decomposition of the organic materials in the subsurface tier (the zone approximating 40–100 cm) into Fibrists, Hemists, or Saprists. Within the United States, some 314 soil series have been established for Histosols. Table 33.8 shows the distribution of those 314 series among the classes of the various

TABLE 33.7 Criteria Utilized in the Classification of Histosols

Suborder	Great Group	Subgroup	Family
Degree of saturation with water	Soil temperature regime	Thickness of organic materials (Terric vs. Typic)	Particle size and mineralogy (used only for Terric subgroups or for those containing Limnic materials)
Degree of decomposition of the subsurface tier	Special components (sphagnum fibers, sulfidic materials or sulfuric horizon, humilluvic materials)	Underlying materials Special materials contained (Limnic) Intergrades to other great groups (Cryic and Sphagnic)	Reaction (pH in 0.01 M CaCl₂) Temperature regime Soil depth (only used if <50 cm deep)

TABLE 33.8 Number of Soil Series in the United States That Are Classified into Particular Taxonomic Groups

Suborders		Great Groups		Subgroups	
Formative Element	Number of Series	Formative Element	Number of Series	Formative Element	Number of Series
Fibrists	26	Cryo	58	Fluvaquentic	14
Folists	35	Haplo	198	Limnic	19
Hemists	82	Sphagno	7	Lithic	37
Saprists	171	Sulfi	17	Terric	124
		Udi	19	Typic	102
		Usti	7	Hemic	7
		Others	8	Others	11
Total	314	Total	314	Total	314

taxonomic categories. The number of series that exist within a particular class may result from many factors and should not be taken to represent the areal extent of those soils. Histosols classified at the family level are differentiated into classes based upon particle size and mineralogy (used only for terric subgroups or for those containing limnic materials), reaction (pH in 0.01 M CaCl$_2$), temperature regime, and soil depth (only used if <50 cm deep).

33.2.7 Biological and Chemical Properties

Organic carbon contents are generally higher and nitrogen contents lower in less-decomposed peats than highly decomposed peats (Table 33.9). As a result, C:N ratios are generally higher for less-decomposed peats (Table 33.9; Lee et al., 1988). The ash content (mineral component) is also higher for more highly decomposed peats (Table 33.9; Lévesque et al., 1980; Lee et al., 1988). Thus, more highly decomposed peats are generally more fertile than less-decomposed peats. Some drained, sapric peats may supply nitrogen in excess of crop requirements without fertilization. However, nutrients derived from minerals, such as phosphorus, potassium, and most micronutrients, are frequently deficient in Histosols (Lucas, 1982; Yefimov, 1986).

The chemical and physical properties of peats are also related to their botanical composition. Peats derived mostly from *Sphagnum* mosses tend to be more acid, less decomposed, contain less ash, have lower cation exchange capacity (CEC), and have lower bulk density than woody peats; sedge peats typically have intermediate properties (Farnham and Finney, 1965; Lévesque et al., 1980).

33.2.7.1 Soil Carbon

Interest in the global C cycle has focused attention on the high proportion (3/4) of terrestrial C stored in soils (Lal et al., 1995). As a group, wetland soils maintain a disproportionately high level of soil carbon, and Histosols, which are composed largely of organic matter, clearly store the largest quantities of soil

carbon. Although peatlands only occupy approximately 4% of the global land surface, they store about 30% of the global soil C (Lavoie et al., 2005). While typical agricultural soils may contain between 2 and 10 kg C m^{-2}, reported values for Histosols typically are an order of magnitude greater, with some values >200 kg C m^{-2} (Table 33.10). The quantity of C stored in some very deep Histosols is undoubtedly even higher.

Histosols are very dynamic and may be particularly significant in the overall terrestrial C budget. Many Histosols continue to sequester C at significant rates. This is particularly true for soils of coastal marshes, where rising sea level continues to power the engines of marsh accretion and C storage. Therefore, Histosols are generally viewed as a significant C sink although some studies indicate that climate change either through increased frequency and intensity of fire (Turetsky et al., 2002) or through elevated decomposition as a result of rising temperatures (Billett et al., 2004) is possibly switching some peatlands to sources of C to the atmosphere. In addition, if Histosols are drained or in some other way exposed to an aerobic environment, they may begin to oxidize and yield large quantities of C to the atmosphere (e.g., Nykanen et al., 1997), although other studies indicate that drainage can increase C sequestration as a result of greater aboveground and belowground productivity (e.g., Minkkinen and Laine, 1998).

Most of the discussion of possible global warming and greenhouse gas emission has focused on rising levels of CO$_2$ in the atmosphere. Methane (CH$_4$), however, is 32 times more efficient than CO$_2$ in trapping infrared radiation. Because many Histosols are strongly reducing (low Eh), they represent an ideal environment for the formation of CH$_4$. In systems where SO$_4^{2-}$ is more abundant in the soil solution, such as in coastal or estuarine environments, sulfate reduction is favored over methanogenesis and methane production may be more limited (Bartlett et al., 1987; Widdell, 1988; Dise and Verry, 2001). However, in many freshwater or inland areas, Histosols may be the locus of significant methane emission to the atmosphere (Table 33.11). Minerotrophic fens have higher methane

TABLE 33.9 Chemical Properties of Organic Soil Material as Related to Degree of Decomposition: Mean (Standard Deviation, N)[a]

emissions than ombrotrophic bogs (Dise, 1993). Methane emission from Histosols seems to be directly related to the location of the water table, with greater generation when soils are saturated to or above the surface (Updegraff et al., 2001; Strack et al., 2004). Greater methane emissions occur when soils are saturated. If aerobic zone exists in the profile, soil microbes will utilize the methane as it passes through on its way to the soil surface. Carbon dioxide emissions, which are produced by oxidation of soil organic matter, have been found to be both greater (Nykanen et al., 1997) and unchanged (Updegraff et al., 2001; Strack and Waddington, 2007) following the lowering of water tables.

33.2.7.2 Sulfides

The biogeochemical environment in which Histosols form can also be conducive to the formation of sulfides. The occurrence of iron sulfides can, in some circumstances, lead to the generation of extreme acidity and acid sulfate soils (Van Breemen, 1982).

Sulfate reduction generally requires the presence of organic matter, which serves as an energy source, low redox potentials, sulfate that functions as an electron acceptor, and sulfate reducing bacteria (Rickard, 1973). If sulfide is formed in the presence of a reactive iron source, then such minerals as pyrite (FeS$_2$) can form. The C source and anaerobic conditions are almost always present in Histosols, but sulfate (SO$_4^{2-}$) levels may vary dramatically among environments. Many inland Histosols receive SO$_4^{2-}$ only in small amounts as atmospheric deposition, and under these circumstances, sulfidization (Rabenhorst and James, 1992) is insignificant, and most of the S in those soils is bound in organic S forms (Novak and Wieder, 1992). Some inland peats have developed acid sulfate conditions, although usually they are associated with deposits of coprogeneous earth (Lucas, 1982). Sulfate reduction is common in coastal Histosols, which contain an abundance of SO$_4^{2-}$ from sea water. Extensive areas of these Sulfihemist soils have been identified along the Atlantic coast of the United States. The distribution of pyrite within

coastal Histosols can be highly variable and is often related to microsite differences in the availability of either reactive iron or sulfide (Rabenhorst and Haering, 1989).

33.2.7.3 Acidity and Base Saturation

In bog Histosols, where inputs of bases are minimal because soil water is derived from rainfall that has never contacted mineral soil, base saturation is low (at least in the rooting zone) and the organic acids produced by partial decomposition of organic matter typically buffer soil water pH near 4; the soil pH in $CaCl_2$ is typically 3–4 (Figures 33.8 and 33.9; Gorham et al., 1985; Urban, 1987). Minerotrophic (fen) peats have higher base saturation,
FIGURE 33.8 Frequency distribution of pH in peatland surface water for 232 sites in Minnesota. Samples with surface water pH near 4 are from bogs and those with pH above 5 are from fens (unforested) and swamps (forested). (From Swanson, D.K., and D.F. Grigal. 1989. Vegetation indicators of organic soil properties in Minnesota. Soil Sci. Soc. Am. J. 53:491–495.)
FIGURE 33.9 Relationship between base saturation and pH of organic soil horizons of Histosols. Peat samples with pH in $CaCl_2$ of less than 4.5 (presumably deposited in bogs) generally have less than 50% base saturation. Peat samples with pH greater than 4.5 (deposited in fens and swamps) typically have high base saturation. Data are for all organic horizons of Histosols in the USDA Natural Resources Conservation Service, National Soil Survey Laboratory characterization database.

and pH in water is generally above 5 ($CaCl_2$ pH above 4.5). The pH of minerotrophic peats is buffered by cation exchange within the soil (Bloom et al., 1983) or by carbonates if they are present. The aluminum ion, which is derived from silicate minerals, comprises a small proportion of the total acidity in most Histosols because of its low solubility at pH > 5.5 (Table 33.9). Less-decomposed peats generally have lower pH than more highly decomposed peats (Table 33.9; Lee et al., 1988).

The distinction between euic and dysic reaction classes at the family level in *Soil Taxonomy* separates the highly acid, bog peats (dysic) from less acid fen peats (euic) (Farnham and Finney, 1965). Because a pH (in $CaCl_2$) greater than 4.5 anywhere in the control section (i.e., anywhere within 130 or 160 cm of the surface) places the soil into the euic class, a bog with a highly acidic near-surface rooting zone may classify as euic rather than dysic due to the presence of higher pH horizons at depth in the soil.

Histosols which contain sulfide minerals such as pyrite have the potential to develop extreme acidity. Under saturated and anaerobic conditions, such sulfide bearing soils have circumneutral pH. If it is drained, dredged, or in some other way exposed to oxidizing conditions, the soil will undergo acid sulfate weathering, a process that is the result of sulfide mineral oxidation and the concomitant production of sulfuric acid (Van Breemen, 1982). The oxidation of pyrite can lead both to the extreme acidification of the soil (pH < 3.5) and also to the generation of acidity, which can be moved offsite through mobilization of acid generating soluble salts such as $FeSO_4$.

33.2.7.4 Cation Exchange Capacity

The CEC of Histosols is quite high as a result of the high cation exchange of organic matter (Table 33.9). The CEC is higher for more highly decomposed peats than fibric peats (Table 33.9; Lévesque et al., 1980). The difference between the CEC of sapric and fibric peats is even more dramatic if the CEC is expressed on a volume rather than mass basis, as a result of the very low bulk densities of fibric materials (Table 33.9). The CEC per unit soil volume is a more useful measure than CEC per unit soil mass in Histosols, because their bulk densities are very low and because roots occupy a volume rather than mass of soil. The CEC per unit volume of fibric peats, near 20 $cmol_c$ L^{-1}, is comparable to that of most mineral soils (5–20 $cmol_c$ L^{-1}) assuming mineral soil bulk density of 1.0–1.5 kg L^{-1} (Holmgren et al., 1993). Even when expressed per unit volume, the average CEC of sapric and hemic peats (Table 33.9) is much higher than the 5–20 $cmol_c$ L^{-1} of most mineral soils.

33.2.8 Physical Properties

33.2.8.1 Bulk Density

The physical properties of Histosols differ greatly from those of mineral soils. Bulk densities for organic soil materials generally are quite low, ranging from as little as 0.02 up to 0.8 g cm^{-3} (Table 33.12). Bulk density is related to the degree of decomposition

of the organic materials with bulk density generally increasing as the materials become more highly decomposed (Figure 33.10). Because organic materials contain varying amounts of mineral matter, this also can affect the bulk density of organic soil horizons. For coastal marsh peat, the organic matter content is generally about twice the content of organic C, with the remainder representing the mineral fraction. Figure 33.11 illustrates the relationship between the mineral content (roughly the difference remaining from twice the OC content) and the bulk density for Oe and Oa horizons from Sulfihemists along the Atlantic Coast (Griffin and Rabenhorst, 1989).

33.2.8.2 Porosity, Hydraulic Conductivity, and Water Retention

Histosols have very high porosity levels, which can reach over 80% as shown by the water content at saturation (Figure 33.12; Boelter, 1969). The high porosity and low bulk density of organic
FIGURE 33.10 Relationship between bulk density of organic materials and indices of decomposition such as rubbed fiber content or pyrophosphate index. (Derived from Buttler, A., H. Dinel, and P.E.M. Levesque. 1994. Effects of physical, chemical and botanical characteristics of peat on carbon gas fluxes. Soil Sci. 158:365–374.)
FIGURE 33.11 The effect of mineral content (roughly the difference remaining from 2× the OC content) on the bulk density of Oe and Oa horizons from Sulfihemists along the Atlantic Coast. Dashed lines represent 12% and 18% OC, which is necessary for soil materials to be considered organic. (Derived from Griffin, T.M., and M.C. Rabenhorst. 1989. Processes and rates of pedogenesis in some Maryland tidal marsh soils. Soil Sci. Soc. Am. J. 53:862–870.)
FIGURE 33.12 Volumetric soil water content as a function of unrubbed fiber content at various moisture tensions. (After Boelter, D.H. 1969. Physical properties of peats as related to degree of decomposition. Soil Sci. Soc. Am. J. 33:606–609.)

soils would lead one to expect high rates of water transmission through Histosols. Weakly or undecomposed peat often has a fairly high hydraulic conductivity; however, as the material becomes more decomposed, the hydraulic conductivity decreases (Table 33.12). The hydraulic conductivity of sapric and some hemic peats is quite low, comparable to that of clay (i.e., 10^{-5} m s^{-1} or less). Because the peat in the lower part of Histosol profiles is often sapric or hemic, little deep percolation occurs and water tends to evaporate or move laterally through the less decomposed, surface horizons (Ivanov, 1981).

Water retention in Histosols is also closely related to the degree of decomposition (Figure 33.12). The large pores of slightly decomposed peats drain readily at low suction. In contrast, the fine pores of more well-decomposed peats retain considerable water at low suctions (Boelter, 1974). The water retention difference (water content at 0.01 MPa minus that at 1.5 MPa suction; approximates plant-available soil water capacity) of most Histosols is very high, approaching 50% in some peats and exceeding 25% in all others except the least-decomposed peats (Figure 33.12).

33.2.9 Utilization and Management of Histosols

33.2.9.1 Interest in Preservation as Coastal and Nontidal Wetlands

Apart from any benefits which may be achieved from managed systems, such as commercial forestry, grazing, or intensive agriculture, Histosols perform a number of environmental and ecological functions. Because most Histosols occur in wetland environments, they typically provide wetland functions including wildlife habitat, floodwater control, groundwater recharge, nutrient and biogeochemical cycling, ion sorption, purification of surface and shallow groundwater, as well as functioning as an important sink for terrestrial C. The importance of peatlands as

paleoenvironmental and archaeological archives has also been documented (Godwin, 1981). Throughout the years, the value society has placed on these functions has been minimal, and the Histosols of peatlands and coastal marshes have been exploited and extensive areas have been destroyed. More recently, people have recognized that the functions which Histosols perform in a natural setting have significant benefit for society. Thus, legislation has been passed in the United States and elsewhere to preserve Histosols and other wetlands.

33.2.9.2 Histosols as Agricultural Resources

As was mentioned earlier, Histosols are utilized as important agricultural soils in many areas, so long as water tables can be effectively managed. For example, in Japan, there are over 70,000 ha of rice that is grown on peatlands. Peatlands in a number of tropical countries such as Cuba, Guyana, Malaya, and Indonesia have been reclaimed from mangroves and are used for the production of sugarcane (Moore and Bellamy, 1974). Within the United States, there has also been extensive growth of vegetables on peatlands in the Northern United States (such as Michigan), and there has also been extensive agricultural development in the Everglades region of Florida. The agricultural use of Histosols presents some special challenges regarding nutrient management and fertility, but the most significant problem is the high water tables requiring drainage.

33.2.9.3 Impacts of Drainage

Where Histosols have been converted for higher intensity land uses, such as in agriculture, horticulture, or silviculture, they are almost always drained to lower the water table. Such drainage results in a number of short-term effects, such as shrinkage and consolidation due to desiccation, the loss of the buoyant force of groundwater, and compaction. There is also ongoing consolidation and soil alteration caused by the enhanced decomposition of the organic materials following the shift from an anaerobic to an oxidizing regime (Stephens and Speir, 1969; Minkkinen and Laine, 1998). Reported rates of long-term peat subsidence range up to 10 cm year^{-1} but most reports are in the range of 2–5 cm year^{-1} (Table 33.13). This consolidation is accompanied by changes in the physical properties of the peat, including higher bulk densities and lower moisture contents.

33.2.9.4 Histosols as Energy Resources

Peat is mined mainly in northern Europe and used as fuel (Table 33.14). In addition, there is extensive mining and export of peat as a horticultural amendment. Important examples of the latter uses include ingredients for potting soils, and mixed fertilizers, components of mushroom beds, as a seed inoculant, as a material for packing of flowers and other plants as well as a general soil amendment to increase organic matter content in gardens, golf courses, etc. Approximately 635,000 metric tons of peat are utilized annually for these types of uses in the United States (Public communication, 2009c).

33.2.9.5 Engineering Properties

Histosols are notorious for their low strength and great compressibility, which make them poor foundation materials for

roads, buildings, and other structures. Compression and settlement of peats may continue for years after loading (MacFarlane, 1969; MacFarlane and Williams, 1974; Dhowian and Edil, 1980). Special engineering techniques, such as removal of the peat or precompression before construction, are thus required. The high water content and acidity of most Histosols also make corrosion of concrete and metal structures a potential problem (MacFarlane, 1969; MacFarlane and Williams, 1974). While Histosols are poor foundation materials, their high porosity and great adsorption capacity make them very useful for treatment of wastewater. Peats have potential for treatment of municipal effluent and removal of heavy metals and hydrocarbon pollutants from wastewater (Malterer et al., 1996).

33.3 Andisols

Paul A. McDaniel

David J. Lowe

Olafur Arnalds

Chien-Lu Ping

33.3.1 Introduction

Andisols are soils that typically form in loose volcanic ejecta (tephra) such as volcanic ash, cinders, or pumice. They are characterized by andic properties that include physical, chemical, and mineralogical properties that are fundamentally different from those of soils of other orders. These differences resulted in a proposal to recognize these soils at the highest level in the USDA soil classification system (Smith, 1978). In 1990, Andisols were added to *Soil Taxonomy* as the 11th soil order (Soil Survey Staff, 1990; Parfitt and Clayden, 1991). A very similar taxonomic grouping, Andosols, is 1 of the 32 soil reference groups recognized in the World Reference Base for Soil Resources (IUSS Working Group WRB, 2006). Andisols (and Andosols) are classified on the basis of selected chemical, physical, and mineralogical properties acquired through weathering and not on parent material alone. Both soil names relate to two Japanese words, *anshokudo* meaning "dark colored soil" (*an*, dark; *shoku*, color or tint; *do*, soil) and *ando* meaning "dark soil." *Ando* was adopted into western soil science literature in 1947 (Simonson, 1979).

The central concept of Andisols is one of deep soils commonly with depositional stratification developing mainly from ash, pumice, cinders (scoria), or other explosively erupted, fragmental volcanic material (referred to collectively as tephra) and volcaniclastic or reworked materials. Andisols occur much less commonly on lavas. Unlike many other soils, Andisol profiles commonly undergo "upbuilding pedogenesis" as younger tephra materials are deposited on top of older ones. The resulting profile character is determined by the interplay between the rate at which tephras are added to the land surface and classical "top-down" processes that form soil horizons. Understanding Andisol

genesis in many instances thus requires a stratigraphic approach combined with an appreciation of buried soil horizons and polygenesis.

The coarser fractions of Andisols are often dominated by volcanic glass. This glass weathers relatively quickly to yield a fine colloidal or nanoscale fraction (1–100 nm) dominated by short-range order materials composed of "active" Al, Si, Fe, and organic matter, especially humus. Previously described erroneously as "amorphous," short-range order materials comprise extremely tiny but structured nanominerals, the main ones being allophane and ferrihydrite (Hochella, 2008). A useful collective descriptor for them is "nanocrystalline" (Michel et al., 2007). Another colloidal constituent, imogolite, comprises long filamental tubes and therefore has both short- and long-range order (Churchman, 2000). The nanominerals, chiefly allophane, ferrihydrite, and metal–humus complexes, are responsible for many of the unique properties exhibited by Andisols.

Despite covering less of the global ice-free land area than any other soil order (~1%), Andisols generally support high population densities, about 10% of the world's population (Ping, 2000). This is because they typically have exceptional physical properties for plant growth and, in many localities, high native fertility because relatively frequent additions of tephra can renew potential nutrient sources (Ugolini and Dahlgren, 2002; Dahlgren et al., 2004). The majority of Andisols occur in humid regions where there is adequate rainfall. Andisols often have high organic carbon contents. These and other factors make Andisols generally well suited for agriculture production and historically allowed establishment of nonshifting agricultural practices. Despite their generally favorable properties for plant growth, Andisols do pose some engineering and fertility challenges. These soils have low bulk densities, resulting in low weight-bearing capacity. Andisols also exhibit thixotropy and sensitivity, properties that cause them to behave in a fluid-like manner when loading pressures are applied (Neall, 2006; Arnalds, 2008). Andisols may exhibit substantial fertility limitations, including

P fixation, low contents of exchangeable bases (especially K) and other nutrients, and strong acidity and Al toxicity (Shoji and Takahashi, 2002; Dahlgren et al., 2004; Lowe and Palmer, 2005).

33.3.2 Geographic Distribution

Andisols cover approximately 124 million ha or about 0.84% of the Earth's ice-free surface (Soil Survey Staff, 1999). They are closely associated with areas of active and recently active volcanism, and their global distribution is depicted in Figure 33.13. The greatest concentration of Andisols is found along the Pacific Ring of Fire, a zone of tectonic activity and volcanoes stretching from South through Central and North America via the Aleutian Islands to the Kamchatka Peninsula of Russia through Japan, Taiwan, the Philippines, and Indonesia to Papua New Guinea and New Zealand. Other areas include the Caribbean, central Atlantic ridge, northern Atlantic rift, the Mediterranean, parts of China, Cameroon, the Rift Valley of east Africa, and southern Australia (Soil Survey Staff, 1999). There are numerous volcanic islands where Andisols are common, including Iceland, the Canary Islands, Azores, Galapagos Islands, Hawaiian Islands, the West Indies, and various small islands in the Pacific.

The global distribution of Andisols encompasses a wide variety of climatic conditions—cold-to-hot and wet-to-dry. This suggests that climate is less important to the formation of Andisols than is proximity to volcanic or pyroclastic parent materials. Nevertheless, the majority of Andisols are found in higher-rainfall regions of the world. Almost two-thirds of Andisols occur in humid regions (udic soil moisture regimes) while fewer than 5% occur in aridic moisture regimes (Mizota and van Reeuwijk, 1989; Wilding, 2000). Approximately half of the world's Andisols occur in the tropics, with the remaining half being split between boreal and temperate regions (Wilding, 2000; IUSS Working Group WRB, 2006).

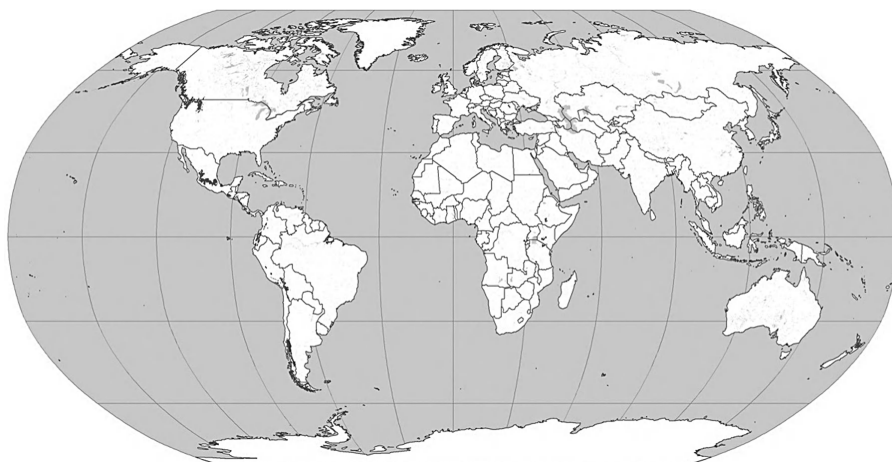
There are almost 15.6 million ha of Andisols in the United States (Soil Survey Staff, 1999). The largest areas occur in Alaska


FIGURE 33.13 Global distribution of Andisols. (Courtesy of USDA-NRCS, Soil Survey Division, World Soil Resources, Washington, DC, 2010.)

(~10 million ha) and in Washington, Oregon, Idaho, northern California, and western Montana (Pewe, 1975; Rieger et al., 1979; Ping et al., 1989; Southard and Southard, 1991; Ugolini and Dahlgren, 1991; Goldin et al., 1992; Takahashi et al., 1993; McDaniel and Hipple, 2010). In the Pacific Northwest region of Washington, Idaho, and Oregon, most Andisols are forested and occur at mid-to-high elevations in cooler temperature regimes (McDaniel et al., 2005). Few Andisols are found in warmer temperature regimes because the summers are normally too hot and dry to allow sufficient weathering or leaching to produce the required andic properties.

Iceland contains ~7 million ha of Andisols. These represent the largest area of Andisols in Europe (Arnalds, 2004). Andisols also occur in France, Germany, Spain, Italy, and Romania (Buol et al., 2003; Kleber et al., 2004; Quantin, 2004; IUSS Working Group WRB, 2006; Arnalds et al., 2007). In New Zealand, ~3.2 million ha of Andisols occur on the North Island, the majority now supporting agriculture or forestry (Parfitt, 1990; Lowe and Palmer, 2005). Japan has ~6.9 million ha of Andisols (Wada, 1986; Takahashi and Shoji, 2002).

Some soils classified as Andisols are also found in humid areas not associated with volcanic activity such as in the southern Appalachian Mountains, parts of Kyushu (Japan), Scotland, Spain, and the Alps. These soils have large quantities of Al or Fe associated with humus (see Section 33.3.3.2) and similar management constraints as those of soils formed from volcanic ejecta and also key out as Andisols. These attributes further highlight the importance of realizing that Andisols are not classified on parent material but on the properties acquired during weathering and leaching. By the same token, soils other than Andisols, such as Entisols, Inceptisols, Spodosols, Mollisols, Oxisols, Vertisols, Alfisols, or Ultisols, may form in association with volcanic or pyroclastic materials (e.g., Shoji et al., 2006).

33.3.3 Andisol Properties

33.3.3.1 Morphological Features

Most Andisols have distinct morphological features. They usually have multiple sequences of horizons (Figure 33.14) resulting from the intermittent deposition of tephras and ongoing top-down soil formation referred to as upbuilding pedogenesis (see Section 33.3.5.1). A horizons are typically dark, often overlying reddish brown or dark yellowish brown Bw cambic horizons. Buried A–Bw sequences are common (Figure 33.14). Layers representing distinct tephra-fall events are common, often manifested as separate Bw horizons or as BC or C horizons if the tephra shows limited weathering or is relatively thick. Horizon boundaries are typically distinct or abrupt where these thicker layers occur.

Andisols are usually light and easily excavated because of their low bulk density and weakly cohesive clay minerals. The high porosity allows roots to penetrate to great depths. Andisols
FIGURE 33.14 Andisol profiles (a) allophanic Taupo soil (Udivitrand) from New Zealand (scale divisions = 10 cm) and (b) nonallophanic Tohoku Farm soil (Melanudand) from Japan with thick (~1 m), dark, strongly humified horizons (melanic epipedon).

generally have granular structures in A horizons, but the structure in Bw horizons is generally weak subangular blocky, often crushing readily to crumb structure. Some Andisols (Udands) formed in areas of high rainfall have higher clay contents while soils that are subjected to wet and dry cycles form prismatic structures. At higher water contents, soils containing as little as 2% allophane have a characteristic greasy feel (Parfitt, 2009), an indication of sensitivity.

33.3.3.2 Mineralogical Properties

Tephra parent materials weather rapidly to form nanominerals that are responsible for many of the unique physical and chemical properties associated with Andisols. Although a wide range of clay minerals can be found in Andisols (such as gibbsite, kaolinite, vermiculite, smectite, crystalline Fe oxides such as hematite and goethite, and cristobalite), those of greatest interest are allophane, imogolite, ferrihydrite, and the Al– and Fe–humus complexes because they confer the characteristic andic properties (Dahlgren et al., 2004; Parfitt, 2009).

Allophane is nearly X-ray amorphous, but under an electron microscope it is structured over short distances, appearing as nanoparticles of hollow spheres 3.5–5 nm in diameter that have the chemical composition $(1–2)SiO_2 \cdot Al_2O_3 \cdot (2–3)H_2O$ (Figure 33.15a) (Wada, 1989; Churchman, 2000; Brigatti et al., 2006; Theng and Yuan, 2008). The most common type of allophane is the so-called Al-rich allophane with an Al:Si molar ratio of ~2 (it is sometimes called proto-imogolite allophane). There is also Si-rich allophane with an Al:Si ratio ~1 (also referred to as halloysite-like allophane).

Imogolite has the composition $(OH)SiO_3 \cdot Al_2(OH)_3$ and has both long- and short-range order. Under an electron microscope, it appears as long smooth and curved hollow threads or tubules with inner and outer diameters of ~0.7 and 2 nm, respectively
FIGURE 33.15 Micrographs of (a) allophane and (b) imogolite (external diameter of nanotubes is ~2 nm). (Reproduced with the kind permission of the Mineralogical Society of Great Britain and Ireland from a paper by Parfitt, R.L. 2009. Allophane and imogolite: Role in soil biogeochemical processes. Clay Miner. 44:135–155. With permission.)

(Figure 33.15b). These nanotubes typically appear as bundles of two or more threads 10–30 nm thick and several micrometers long (Theng and Yuan, 2008). Imogolite in Japan can be seen with the naked eye as a whitish gel film infilling pores in coarse pumice particles (Wada, 1989).

Allophane and imogolite both have high surface areas, ranging from 700 to 1500 m^2 g^{-1} (Parfitt, 2009), and this feature, coupled with their variable surface charge characteristics and exposure of $(OH)Al(OH_2)$ groups at wall perforations (defects), explains their strong affinity for water, metal cations, organic molecules, and other soil minerals (Harsh et al., 2002; Theng and Yuan, 2008). Even small amounts contribute huge reactive surface areas in soils (Lowe, 1995). Allophane and imogolite are soluble in ammonium (acid) oxalate solution, and the Si dissolved is used to estimate their contents in soils (Parfitt and Henmi, 1982; Parfitt, 2009). *Soil Taxonomy* uses oxalate-extractable Al (and Fe) to help define andic soil properties (see Figure 33.16 and Section 33.3.4). Allophane content of B horizons is quite

variable, ranging from about 2% in slightly weathered or metal–humus-dominated systems to >40% in well-developed Andisols. It typically increases with depth in upper subsoils, usually being highest in the Bw and buried horizons. But in many Andisol profiles in New Zealand, allophane decreases and halloysite concomitantly increases with depth in lower subsoils either because of the downward migration of Si into lower profiles or because of changes in climate during upbuilding, or both. Imogolite is more commonly found in B horizons under carbonic acid weathering regimes than in A horizons where organic acid weathering dominates (Dahlgren et al., 2004). Allophane may occur dispersed as groundmass, as coatings, bridges, or infillings (in vesicles or in root channels), or it may be disseminated through pseudomorphs of glass or feldspar grains (Jongmans et al., 1994, 1995; Bakker et al., 1996; Gérard et al., 2007).

Ferrihydrite is common in many Andisols, especially those associated with more basic parent materials, has a composition of $Fe_5HO_8 \cdot 4H_2O$ and imparts a reddish brown color (hues of 5YR–7.5YR; Bigham et al., 2002). Made up of spherical nanoparticles 2–5 nm in diameter (Schwertmann, 2008), ferrihydrite has large, reactive surface areas ranging from ~200 to 500 m^2 g^{-1} (Childs, 1992; Jambor and Dutrizac, 1998). Its abundance is commonly estimated from the amount of Fe extracted by ammonium oxalate solution multiplied by 1.7 (Parfitt and Childs, 1988). It is a widespread and characteristic component of young Fe-oxide accumulations precipitated from Fe-rich solutions in the presence of organic matter, such as in Iceland (Arnalds, 2004), and elsewhere, including New Zealand, Japan, and Australia where its precipitation may be inorganic or bacteria-driven (Childs et al., 1991; Lowe and Palmer, 2005). Ferrihydrite can transform to hematite via solid-state transformation or goethite through dissolution and reprecipitation (Schwertmann, 2008).

Metal–humus complexes are significant components of some Andisol colloidal fractions. These Al- and Fe-organic complexes are immobile and accumulate in dark or black surface horizons where organic materials are abundant, and dark (melanic) horizons may extend to depths as much as 2 m (see Figure 33.14b). Metal–humus complexes represent the active forms of Al and Fe in nonallophanic Andisols as described below (Dahlgren et al., 2004).
FIGURE 33.16 Andic soil properties as defined by *Soil Taxonomy*. (From Soil Survey Staff. 2010. Keys to soil taxonomy. 11th edn. USDA-NRCS, Washington, DC.)

Halloysite is a relatively fast-forming 1:1 layer silicate that often exhibits tubular or spheroidal morphology (White and Dixon, 2002; Joussein et al., 2005). Its formation is favored in seasonally dry environments where higher Si concentrations are maintained (Shoji et al., 1993). These include areas of lower rainfall, restricted drainage, and Si-rich parent materials (Lowe, 1986; Churchman, 2000; Churchman and Lowe, 2011, Section 20.1). Halloysite surfaces are characterized by some permanent negative charge, allowing retention of cations across a wide range of pH values.

The soil solution in Andisols in a range of locations may contain large amounts of dissolved Si, which leads to the formation by nucleation of secondary silica minerals from the saturated solution (Ping et al., 1988; Shoji et al., 1993; Ping, 2000; Nanzyo, 2002, 2007; Waychunas and Zhang, 2008). Termed laminar opaline silica, this material is circular or elliptical in shape (0.2–0.5 μm diameter) and extremely thin. Precipitation of the silica may be aided by evaporation or freezing of soil water, or via plant-related processes related to Si uptake and recycling (Lowe, 1986; Drees et al., 1989; Churchman, 2000; Henriet et al., 2008). Such silica polymorphs can be distinguished from biogenic forms of silica (phytoliths) because the latter have more complex shapes inherited from biological cells (Kondo et al., 1994; Nanzyo, 2007).

Andisols dominated by allophane with subordinate imogolite and ferrihydrite in upper horizons are referred to as *allophanic Andisols*. These contrast with a second, strongly acid group known as *nonallophanic Andisols* in which metal–humus complexes dominate the colloidal mineralogy. Nonallophanic Andisols are common in Japan especially where they account for about 30% of soils formed on tephras (Takahashi and Shoji, 2002) and are known in around 20 other countries (Saigusa and Matsuyama, 2004). Examples of soils from each group are shown in Figure 33.14. In Table 33.15, the Thingvallasveit and Tirau soils are examples of allophanic Andisols; the Tohoku Farm soil is an example of a nonallophanic Andisol. The mineralogical differences between these two groups of Andisols lead to several important different physical and chemical properties (especially the strong acidity of nonallophanic Andisols) and significant management implications (Dahlgren et al., 2004).

In the silt and sand fractions of Andisols, the dominant components are volcanic glass (a mineraloid) and various primary minerals. The glass particles (shards) which, like shattered glass, have sharp angles and edges, are very abrasive. However, these glass particles are usually coated with colloidal materials including allophane, ferrihydrite, and other Fe oxides and their humus complexes, which all contribute to aggregate formation. It is noteworthy that volcanic glass is often quite vesicular and porous in nature (as is pumice), and thus can retain water and has more chemical activity than other common sandy materials (Ping, 2000; Lowe and Palmer, 2005).

33.3.3.3 Chemical Properties

One of the common characteristics of Andisols is accumulation of relatively large quantities of organic matter, both in the allophanic (moderate pH) and nonallophanic Andisols (low pH; Table 33.15). Allophanic Andisols typically contain up to ~8%–12% C, whereas nonallophanic soils may contain up to ~25%–30% C (Mizota and van Reeuwijk, 1989). The residence time of C in Andisols, as measured by ^{14}C, is much greater than that of other soil orders (Parfitt, 2009). In addition, upbuilding pedogenesis leads to the storage of C in lower parts of profiles, and especially in buried A horizons that are sealed off and isolated from most surface processes.

Andisols are almost always acid, with most pH (H_2O) values ranging from 4.8 to 6.0 (Shoji et al., 1993; Dahlgren et al., 2004). Uncultivated, nonallophanic Andisols with high organic matter contents typically have a pH (H_2O) < 4.5 (IUSS Working Group WRB, 2006).

One of the key factors affecting the chemistry of Andisols is the variable surface charge associated with the colloidal fraction (Qafoku et al., 2004). Electrical charges on colloid or nanoparticle surfaces can be either positive or negative, and change as a function of pH. Surfaces have positive charge at lower pH and retain anions, while cations are retained by the negative charge at higher pH. This variable charge greatly affects the behavior of ions that are retained in soils. Cation retention capacity of Andisols makes the soils susceptible to metal and radioactive fallout ^{137}Cs pollution (Adamo et al., 2003; Sigurgeirsson et al., 2005). Andisols also exhibit anion exchange properties, which can be important for nutrient retention (e.g., NO_3^- and SO_4^{2-}) (Shoji et al., 1993).

Measured cation exchange capacity of Andisols is relatively high, often 20 to >50 cmol$_c$ kg^{-1}. However, because the dominant colloids have variable charge, much of this CEC is pH dependent. This is especially true in allophanic Andisols (Dahlgren et al., 2004) and means that CEC decreases with decreasing pH. And because most Andisols are acid, CEC measurements made at pH 7 or 8.2 will be artificially high. In andic soils of the Pacific Northwest of United States, average CEC values determined using unbuffered extractants (effective CEC or ECEC) are approximately one-fourth of those determined at pH 8.2, 6.5 cmol$_c$ kg^{-1} vs. 26.4 cmol$_c$ kg^{-1} (McDaniel et al., 2005). This phenomenon needs to be considered when measuring CEC and base saturation or interpreting these data. The relatively low ECEC of Andisols can limit their ability to retain and exchange Ca, Mg, and K. Some representative cation exchange characteristics of Andisols are presented in Table 33.15.

The active Al and Fe compounds in Andisols (allophane/imogolite, metal–humus complexes, and ferrihydrite) also have the ability to sorb and strongly bind anions such as phosphate and fluoride (Shoji et al., 1993; Dahlgren et al., 2004; Parfitt, 2009). Much of this sorption is not reversible, leading to large quantities of phosphate being rendered unavailable for plant uptake. As described in Section 33.3.4, the amount of P retention in soils is used to define andic soil properties (Soil Survey Staff, 2010). Similarly, quantities of active Al and Fe compounds can also be estimated by reacting soil with NaF solution. Sorption of F$^-$ releases OH$^-$ into solution, thereby raising the pH. A resultant pH greater than ~9.5 indicates the presence of allophane/imogolite

and/or Al–humus complexes, and because of this, NaF field test kits can be used for field identification of Andisols (Fieldes and Perrott, 1966; IUSS Working Group WRB, 2006).

33.3.3.4 Physical Properties

Unique physical attributes of Andisols are related to structural assemblages of hollow spheres and tubular threads as mineral entities into resilient, progressively larger (silt-sized) aggregated domains. This aggregation results in low density, high porosity, high surface area, and high soil water retention even at low water potentials. The structural arrangement accounts for the low thermal conductivity of andic materials, which is three to four times less than that of the phyllosilicates in other mineral soils. It also accounts for the thixotropic and sensitivity character of these soils and several irreversible changes in physical properties that occur upon drying (Ping, 2000; Neall, 2006).

Andisols have low bulk density, usually <0.9 g cm^{-3}, because of the high organic matter and nanomineral contents (Table 33.16) and well-developed aggregation. This results in good tilth and makes them excellent rooting media. On the other hand, low bulk densities result in low weight-bearing capacity and make Andisols highly susceptible to wind and water erosion when surface cover is removed or degraded (Ping, 2000; Nanzyo, 2002; Dahlgren et al., 2004; Neall, 2006). Because of the nature of volcanic ejecta and its distribution, many Andisols in proximal locations contain appreciable amounts of gravel and stones, and coarse-grained tephra layers may have adverse effects on hydrological properties by interrupting capillary movement of water. Some additional adverse physical properties include a high glass content that can reduce the quantity and biodiversity of soil organisms such as earthworms, and the presence occasionally of impenetrable horizons such as thin Fe pans (placic horizons) in higher rainfall areas (Neall, 2006).

Andisols typically exhibit high water retention because of the presence of allophane, ferrihydrite, and metal–humus complexes, which have high surface areas as noted previously. As a result, moisture contents of many Andisols can exceed 100% on a weight basis, even at soil moisture tensions of 1500 kPa—this feature is illustrated by the data for the Hilo soil (Table 33.16). Water retention is greatest in Andisols that have undergone significant weathering and hence have high clay contents.

Most field-moist Andisols have a greasy feel when rubbed between the fingers and exhibit smeariness—these can be both indicators of the properties known generally as sensitivity and thixotropy (Soil Survey Staff, 1975; Torrance, 1992). Thixotropy is a reversible gel–sol transformation that occurs when shear forces are applied to a moist soil. The applied shear force causes the soil to abruptly lose strength, sometimes to the point of behaving as a fluid. When the shear force is removed, the soil will recover some or all of its original strength. Sensitivity (the term used more commonly by engineers) is the ratio of undisturbed to disturbed (remolded) shear strength, that is, the maximum strength of

an undisturbed specimen compared with the residual strength remaining after force or strain is applied (Mitchell and Soga, 2005; Neall, 2006). In sensitive materials, the original strength is generally not recovered—unlike thixotropic materials—after removal of the force. Both sensitivity and thixotropic behavior are best expressed in Andisols having high water retention and lack of layer silicates to provide cohesion and can pose significant engineering problems.

Many Andisols exhibit irreversible changes upon drying. Allophane nanospheres collapse upon dehydration and form larger aggregates that do not break down upon rewetting. This phenomenon can cause crust formation at the soil surface during hot dry periods. It also results in well-known unreliable particle size analyses of air-dried Andisols. Normally, clay content is underestimated and sand and silt contents are overestimated (Ping et al., 1989; Dahlgren et al., 2004). However, reliable sand-, silt-, and crystalline clay-size fraction data were obtainable for andesitic Andisols in New Zealand by Alloway et al. (1992) who analyzed grain-size distributions of residual material following selective dissolution of nanominerals and organic constituents via ammonium oxalate. Other irreversible changes that occur upon desiccation include increases in bulk density, decreases in water retention, and increases in cohesive strength. Note the difference in water retention and bulk density values between dried and moist samples in Table 33.16.

Plasticity in Andisols is different from that of soils containing layer silicate clay minerals. Generally, field-moist Andisols have high liquid (60%–350%) and plastic limits (70%–180%) (Warkentin and Maeda, 1980; Neall, 2006). The low plasticity index (0–10) also clearly separates Andisols from other soils. Plasticity measurements can be used as an index of physical behavior in Andisols and as a substitute for particle size analysis, which usually is not reliable. Air-dry samples, on the other hand, often show low plasticity because of the irreversible changes on drying and behave like sandy soils.

33.3.4 Classification of Andisols

Andisols are classified on the basis of having andic soil properties, which are quantitatively defined in *Soil Taxonomy* (Soil Survey Staff, 2010). In general, andic soil properties consist of combinations of properties that develop as tephras and other volcanic materials weather. These include relatively low bulk density values ($\leq 0.90\,g\,cm^{-3}$), relatively high phosphate retention (>25%–85%), the presence of volcanic glass, and the presence of nanoscale weathering products containing Al, Fe, and Si (Soil Survey Staff, 2010). The criterion of percentage Al extracted by ammonium oxalate (Al_o) plus half the percentage Fe extracted by ammonium oxalate (Fe_o) from short-range order nanominerals is used to quantitatively define andic properties. The quantity $0.5\,Fe_o$ is used to normalize the criterion because Fe has an atomic weight (56), approximately twice that of Al (27). The majority of soils with a glass content and percentage of $Al_o + 0.5Fe_o$ that falls within the shaded area of Figure 33.16 have andic soil properties. Soils possessing at least 36 cm of material

with andic soil properties are classified as Andisols (Soil Survey Staff, 2010). It is emphasized that freshly deposited volcanic ash does not have andic soil properties and would not be classified as an Andisol. It is not until some weathering has occurred—sufficient to generate $Al_o + 0.5Fe_o$ totaling at least 0.4%—that andic properties are developed.

Andisols are separated into suborders primarily on the basis of soil moisture and/or temperature regimes (Table 33.17). Aquands are poorly drained and have a water table at or near the soil surface for much of the year. These soils are usually restricted to low-lying landscape positions and have dark surface horizons. Because of excessive wetness, Aquands typically require drainage in order to be used for crop or pasture production.

Gelands are very cold Andisols that have a mean annual soil temperature (MAST) $\leq 0°C$ (Soil Survey Staff, 2010). Relatively little is known about the distribution of these soils, but they are found at higher latitudes in areas of either current or recent volcanic activity.

Cryands are cold Andisols having a cryic temperature regime ($0°C < MAST \leq 8°C$ and summers are cool; Soil Survey Staff, 2010). They are found at higher latitudes and higher elevations. In the United States, Cryands are found mainly in Alaska and mountainous regions of the Pacific Northwest (Ping, 2000; McDaniel and Hipple, 2010). They are extensive in Iceland (Arnalds and Kimble, 2001) and also on the Kamchatka Peninsula and occur in mountainous regions elsewhere including in eastern Africa, the Andes, and (uncommonly) New Zealand (Ping, 2000; Lowe and Palmer, 2005). Globally, there are ~26 million ha of Cryands, and they are the third most common suborder, representing ~28% of Andisols (Soil Survey Staff, 1999; Wilding, 2000).

Torrands are Andisols of very dry environments where moisture for plant growth is very limited. This lack of soil moisture slows down weathering processes and leaching, thereby inhibiting development of andic soil properties. Torrands are found in Oregon and Hawaii in the United States. They are the least extensive of any of the Andisol suborders, with only ~100,000 ha occupying the global ice-free land area (<1% of Andisols).

Xerands occur in temperate regions with xeric soil moisture regimes, which are characterized by cool, moist winters and very warm, dry summers (Mediterranean climates). In the United States, they occur primarily in northern California, Oregon, Washington, and Idaho where they have formed under coniferous forest. Elsewhere, Xerands occur in scattered localities including Italy, Canary Islands, Argentina, and South Australia (Broquen et al., 2005; Lowe and Palmer, 2005; Inoue et al., 2010). Xerands are uncommon globally (~4% of Andisols).

Vitrands are the only suborder that is not defined by a climatic regime. These Andisols are relatively young and only slightly weathered. They tend to be coarse-textured and have a high content of volcanic glass that may be strongly vesicular or pumiceous. In the United States, Vitrands are found in Washington, Oregon, and Idaho. They also occur in Argentina (Broquen et al., 2005) and are common in the North Island of New Zealand (Lowe and Palmer, 2005). Globally, there are ~28 million ha of Vitrands (~31% of Andisols) making them and

TABLE 33.17   Listing of Andisol Suborders and Great Groups

Suborders	Great Groups
Aquands—poorly drained Andisols with a water table at or near the surface for much of the year	
	Gelaquands—Aquands of very cold climates (mean annual soil temperature <0°C)
	Cryaquands—Aquands of cold climates (0°C < mean annual soil temperature ≤8°C)
	Placaquands—Aquands with a thin pan cemented by Fe, Mn, and organic matter
	Duraquands—Aquands with a cemented horizon
	Vitraquands—Aquands with coarse textures dominated by glassy materials
	Melanaquands—Aquands with a thick, dark, organic matter-rich surface layer
	Epiaquands—Aquands with a perched water table
	Endoaquands—Aquands with a groundwater table
Gelands—Andisols of very cold climates (mean annual soil temperature ≤0°C)	
	Vitrigelands—Gelands with coarse textures dominated by glassy materials
Cryands—Andisols of cold climates (0°C < mean annual soil temperature ≤8°C)	
	Duricryands—Cryands with a cemented horizon
	Hydrocryands—Cryands with very high water-holding capacity
	Melanocryands—Cryands with a thick, very dark, organic matter-rich surface layer
	Fulvicryands—Cryands with a thick, organic matter-rich surface layer
	Vitricryands—Cryands with coarse textures dominated by glassy materials
	Haplocryands—other Cryands
Torrands—Andisols of very dry climates	
	Duritorrands—Torrands with a cemented horizon
	Vitritorrands—Torrands with coarse textures dominated by glassy materials
	Haplotorrands—other Torrands
Xerands—Andisols of temperature regions with warm, dry summers and cool, moist winters	
	Vitrixerands—Xerands with coarse textures dominated by glassy materials
	Melanoxerands—Xerands with a thick, very dark, organic matter-rich surface layer
	Haploxerands—other Xerands
Vitrands—slightly weathered Andisols that are coarse textured and dominated by glassy material	
	Ustivitrands—Vitrands of semiarid and subhumid climates
	Udivitrands—Vitrands of humid climates
Ustands—Andisols of semiarid and subhumid climates	
	Durustands—Ustands with a cemented horizon
	Haplustands—other Ustands
Udands—Andisols of humid climates	
	Placudands—Udands with a thin pan cemented by Fe, Mn, and organic matter
	Durudands—Udands with a cemented horizon
	Melanudands—Udands with a thick, very dark, organic matter-rich surface layer
	Hydrudands—Udands with very high water-holding capacity
	Fulvudands—Udands with a thick, organic matter-rich surface layer
	Hapludands—other Udands

Source: Soil Survey Staff. 2010. Keys to soil taxonomy. 11th edn. USDA-NRCS, Washington, DC.

Udands (similar in extent) the two most extensive suborders (Soil Survey Staff, 1999; Wilding, 2000).

Ustands occur in tropical or temperature regions that have ustic soil moisture regimes. The ustic soil moisture regime is characterized by an extended dry period, but moisture is normally present at a time when conditions are suitable for plant growth (Soil Survey Staff, 2010). Ustands are of fairly limited extent in the United States and are found mainly in Hawaii. They also occur in Mexico, on Pacific islands, and in eastern Africa (Dubroeucq et al., 1998; Takahashi and Shoji, 2002). About 6.3 million ha of Ustands are known globally (~7% of Andisols).

Udands are Andisols with a udic moisture regime, which is common to humid climates. Udands are thus characterized by well-distributed precipitation throughout the year and limited periods of soil moisture stress. In the United States, Udands are found in western parts of Washington and Oregon and in Hawaii. Elsewhere, they occur commonly on other parts of the Pacific Rim including in Patagonia (Argentina), Mexico, Japan, the Philippines, Indonesia, and New Zealand (Takahashi and Shoji, 2002; Van Ranst et al., 2002; Broquen et al., 2005; Prado et al., 2007). In total, Udands occupy nearly ~28 million ha of ice-free land globally (~30% of Andisols; Soil Survey Staff, 1999; Wilding, 2000).

Each of the suborders is further separated into great groups. These are listed and described in Table 33.17. A variety of characteristics are used to define great groups, including the presence or absence of certain types of soil horizons, moisture and temperature regimes, glass content and texture, and water retention.

There are also soils of other orders that have been influenced to a lesser degree by andic materials (Parfitt, 2009). Andic soil properties have developed, but their distribution within the soil is not of sufficient thickness for the soils to be classified as Andisols. These soils are therefore classified as andic subgroups of other orders. In cases where andic materials have been extensively mixed with other parent materials, or andic properties are only weakly expressed, soils are classified as vitrandic subgroups of other soil orders (Soil Survey Staff, 2010). In the United States, such soils are extensive in the Pacific Northwest where they are transitional to higher-elevation, forested Andisols (McDaniel and Hipple, 2010).

33.3.5 Formation of Andisols

33.3.5.1 Parent Material and Stratigraphy

In most cases, the parent materials from which Andisols have formed are of explosive volcanic origin (rather than effusive) and thus fragmental and unconsolidated. Such materials range in size from ash (<2 mm) and lapilli (2–64 mm) through to large angular blocks or part-rounded bombs (>64 mm)—that is, from fine dust to boulders. Collectively, these materials are termed pyroclastic deposits or tephra (Gk *ashes*) (Alloway et al., 2007). Tephra deposits typically are loose and very coarse and thick close to source vents but become markedly finer and thinner with increasing distance away from source so that at more than ~100 km from vent most comprise mainly ash-sized material (equivalent to sand or finer particles). The accumulation at a particular site of numerous tephra deposits from sequential eruptions from one or more volcanoes leads usually to the formation of Andisols with distinctive layered profiles and buried soil horizons, forming multisequal profiles (Figure 33.17). Such layered profiles, together with their andic soil properties, are special features of Andisols. Study of the layers and attaining ages for them (tephrostratigraphy) is an important aspect of understanding Andisol formation (Lowe and Palmer, 2005; Lowe and Tonkin, 2010).

During periods of quiescence between major eruptions, soil formation takes place, transforming the characteristics of the unmodified tephra via normal top-down pedogenesis whereby the materials are altered in a downward-moving front to form subsoil horizons. However, when new tephras are added to the land surface, upbuilding pedogenesis takes place. The frequency and thickness of tephra accumulation (and other factors) determine how much impact the top-down processes have on the ensuing profile character, and if "developmental" or "retardant" upbuilding, or both, will take place. Two contrasting scenarios can be considered.
FIGURE 33.17 Udivitrand (Rotomahana soil) from New Zealand composed of multiple tephra deposits and associated buried soils and horizons; scale divisions = 10 cm; the oldest tephra layer (Rotoma) at bottom of exposure is 9505 ± 25 calibrated years BP.

In the first scenario, successive thin tephra deposits (ranging from millimeters to centimeters in thickness) accumulate incrementally and relatively infrequently, so that developmental upbuilding ensues. Such a situation occurs typically at distal sites. The thin materials deposited from each eruption become incorporated into the existing profile over time. Top-down pedogenesis continues as the tephras accumulate but its effects are lessened because any one position in the sequence is not exposed to pedogenesis for long before it becomes buried too deeply for these processes to be effective as the land surface gently rises (Figure 33.18). This history thus leaves the tephra materials with a soil fabric inherited from when the tephra was part of the surface A horizon or subsurface Bw horizon (Lowe and Palmer, 2005; Lowe and Tonkin, 2010). Each part of the profile has been an A horizon at one point, as illustrated in Figure 33.18.

In the second scenario, tephra accumulation is more rapid, as occurs in locations close to volcanoes, or when a much thicker layer (more than a few tens of centimeters) is deposited from a powerful eruption. In the latter case, the antecedent soil is suddenly buried and isolated beyond the range of most soil-forming processes (i.e., it becomes a buried soil horizon or paleosol). A new soil will thus begin forming at the land surface in the freshly deposited material. This scenario typifies retardant upbuilding, which recognizes that the development of the now-buried soil has been retarded or stopped, and the pedogenic "clock" reset to time zero for weathering and soil formation to start afresh. An example of a multisequal Andisol profile formed via retardant upbuilding pedogenesis since ~9500 calendar
FIGURE 33.18 Model of upbuilding pedogenesis profiles over ~25,000 years in the Waikato region, New Zealand. (From Lowe, D.J., and P.J. Tonkin. 2010. Unravelling upbuilding pedogenesis in tephra and loess sequences in New Zealand using tephrochronology, p. 34–37. *In* Proc. IUSS 19th World Soil Congress, Symposium 1.3.2 Geochronological techniques and soil formation, Brisbane, Australia August 1–6, 2010. Published on DVD and online at: http://www.iuss.org. With permission.)

FIGURE 33.19 Volcanic glass compositions and dissolution of Al and Si to form allophane. (After Hiradate, S., and S.-I. Wada. 2005. Weathering processes of volcanic glass to allophane determined by ^{27}Al and ^{29}Si solid-state NMR. Clays Clay Miner. 53:401–408.)

(cal) years ago is shown in Figure 33.17. Each of five successive tephra deposits shows the imprint of top–down pedogenesis, as depicted by their horizonation. But the sudden arrival of a new deposit every few thousand years or so on average has buried and effectively isolated each of the weakly developed "mini" soil profiles as the land surface rises.

In addition to stratigraphic factors, Andisols are markedly affected by the mineralogical and physicochemical compositions of the parent tephras, or associated deposits derived from remobilization of volcanic and other material (collectively termed volcaniclastic deposits). For example, the marked influence of windblown dust (mainly basaltic glass) on soil properties in Iceland was described by Arnalds (2010). Tephras differ widely according to the chemical makeup of magmas of the volcanoes that generated them. The chemistry of magmas, especially Si content, governs the way a volcano erupts. Three main magma types and resulting eruptives can be identified according to their chemical composition—rhyolitic ($\gtrsim$70% SiO_2), andesitic/dacitic (~50%–70% SiO_2), and basaltic ($\lesssim$~50% SiO_2). All magmas generate volcanic glass, a noncrystalline, easily weatherable mineraloid, and various other primary silicate minerals (Shoji et al., 1993; Nanzyo, 2002; Smith et al., 2006; Alloway et al., 2007; De Paepe and Stoops, 2007). Glass especially provides much of the Si and Al required to dissolve and re-form as allophane or other aluminosilicate clay minerals, and the amounts differ according to the magma composition as shown in Figure 33.19. Feldspars also release Si and Al via weathering for clay formation.

Generally, the basaltic and intermediate tephras tend to weather more readily than rhyolitic tephras, and in all cases glasses weather very quickly (Neall, 1977; Kirkman and McHardy, 1980; Colman and Dethier, 1986; Hodder et al., 1996; Shikazono et al., 2005). Compared with hard rock, the fragmental tephra components, especially vesicular glass and pumice fragments, have a much greater surface area and higher porosity and permeability, and so break down to constituent compounds very readily. As this weathering occurs, various elements including Si and Al are released into chemical solution either for subsequent leaching, complexing with humic materials, plant uptake, or synthesis (neoformation) into relatively stable nanominerals and other clay minerals (Lowe, 1986; Vacca et al., 2003; Dahlgren et al., 2004). Andisols developed on (base-rich) basaltic eruptives are inherently more fertile than those on more siliceous eruptives (Wolff-Boenisch et al., 2004). Weakly weathered tephras give rise to the glass-rich Andisols that belong to the Vitrand suborder.

33.3.5.2 Climate

Climate plays an important role in Andisol formation, and soil moisture and temperature regimes are used to differentiate all the suborders except Vitrands (Ping, 2000). The majority of Andisols, as reported previously, are found under udic soil moisture regimes, and around half are found in the tropics, with the rest occurring in temperate or boreal regions. Climatic conditions help govern the combinations of processes, collectively referred to as andisolization, that occur in soils developing on tephras. Andisolization is the in situ formation of andic soil materials comprising nanominerals composed of "active" Al, Si, Fe, and humus (Dahlgren et al., 2004). The process is discussed in more detail in Section 33.3.6.

The essential conditions for the formation of allophane are the activity of silicic acid in the soil solution, the availability of Al species, and the opportunity for coprecipitation (Figure 33.19). These conditions are controlled largely by the leaching regime, the organic cycle, and pH, which, in turn, are potentially influenced by numerous environmental factors including rainfall, drainage, depth of burial, parent tephra composition and accumulation rate, dust accession, type of vegetation and supply of humic substances, and human activities (such as burning vegetative cover), together with thermodynamic and kinetic factors (Parfitt and Saigusa, 1985; Lowe, 1986, 1995; Hodder et al., 1990; Chadwick et al., 2003; Dahlgren et al., 2004; Parfitt, 2009). Availability of Al, derived mainly from the dissolution of glass or feldspars, is assumed to be unlimited in this model, though potentially more is available from andesitic and especially basaltic tephras than rhyolitic tephras (Lowe, 1986; Shoji et al., 1993; Cronin et al., 1996). In contrast, in pedogenic environments rich in organic matter and with pH ≤ 5, humus effectively competes for dissolved Al, leaving little Al available for coprecipitation with Si to form allophane or halloysite (Shoji et al., 1993; Dahlgren et al., 2004; see Section 33.3.5.4).

In New Zealand, both mineralogical and soil solution studies on soils derived from tephras extending across a rainfall gradient showed that rainfall, coupled with through-profile drainage, helps govern Si concentration [Si] in soil solution and thus the likelihood of allophane being formed or not (Parfitt et al., 1983; Singleton et al., 1989; Parfitt, 2009). The Si leaching model shown in Figure 33.20 is summarized as follows: where [Si] is less than ~10 ppm (mg L^{-1}), allophane is formed; where [Si] is greater than ~10 ppm, halloysite is formed. If [Si] is close to ~10 ppm, then either allophane or halloysite may predominate. A profile throughflow threshold of approximately 250 mm year^{-1} of drainage water likely controls [Si]—less than ~250 mm year^{-1} means that the loss of Si is insufficient for Al-rich allophane to form and halloysite (or Si-rich allophane) forms instead (Parfitt et al., 1984; Lowe, 1995).

It is emphasized, however, that allophane and other nanominerals can form under lower rainfalls (~700 mm year^{-1}) such as in Mexico, Iceland, and South Australia (Arnalds et al., 1995;

FIGURE 33.20 Simplified allophane–halloysite rainfall leaching model.

Dubroeucq et al., 1998; Ugolini and Dahlgren, 2002; Lowe and Palmer, 2005). As well, other factors such as parent tephra composition and vegetation are also important.

33.3.5.3 Topography

Andisols are found on all types of topography and at a wide range of elevations (from sea-level to >3000 m). Because of their strong association with the products of volcanism, Andisols occur most commonly in volcanic landscapes, which can range from mountainous to hilly terrains on the flanks of stratovolcanoes, dome complexes, shield volcanoes, and scoria or tuff cones through to rolling or essentially flat-lying landscapes, some associated with plateaus of tephra-draped welded ignimbrite sheets derived from large caldera eruptions, such as occur for example in the western United States, Japan, and northern New Zealand (Lowe and Palmer, 2005). Because tephras are carried long distances by the wind, and can easily be reworked by wind and water, they can be deposited in a variety of sedimentary and other landscapes including dune plains, fluvial terraces or plains, and flat intermontane valleys (Ping, 2000; Lowe and Palmer, 2005). The thickest tephra-fall deposits tend to be downwind from the volcanic source areas on rolling or flattish land surfaces (Lowe and Palmer, 2005). On hilly landscapes, tephras are variable in thickness because of erosion (especially during the last glaciation), and profiles typically are thinner on slopes than on more stable geomorphic surfaces (Neall, 2006). The effects of specific topographic positions on Andisol formation have been evaluated, for example, by Navarette et al. (2008) in the Philippines.

33.3.5.4 Vegetation

Because Andisols occur in all moisture and temperature regimes on different landscapes at different elevations, vegetation is accordingly highly variable. In general, Andisols are usually moderately acid to very acid and so vegetation associated with acid soils will predominate. Because of their relatively high water-holding capacities, Andisols, even in xerophytic areas, are likely to support more luxuriant vegetation than other nonandic soils in the same environment. When the vegetation cover is grass, a more humus-rich profile usually develops. A thick, dark surface known as a melanic epipedon is common in many Andisols that have formed under grasses. Melanic epipedons contain ≥6% organic C as a weighted average, have black soil colors (melanic index ≤1.70), and attain a thickness of ≥30 cm (Soil Survey Staff, 2010). Andisols with melanic epipedons are usually classified as Melanudands, an example of which is shown in Figure 33.14b.

Although the vegetation on Andisols is quite variable, it clearly has a major influence on the type of Andisol formed (Ping, 2000). In the Pacific Northwest and parts of Alaska, and in New Zealand, Udands generally formed under forest. However, Udands are known to form under other vegetation types such as grasses in south central Alaska (Ping, 2000) and in Japan, where pampas grass (*Miscanthus sinensis*), known as "susuki,"
has formed Melanudands, Sitka spruce (*Picea sitchensis*) Hydrudands, and blue joint grass (*Calamagrostis canadensis*) Fulvudands. The organic matter is dominated by humic acids in the first cases and by fulvic acids in the latter (Ping et al., 1989; Shoji et al., 1993; Nanzyo, 2002; Dahlgren et al., 2004).

In Japan and elsewhere, the humic acids in many Andisols and associated soils are characterized by their stability and aromatic (humified) structure (Shoji et al., 1993; Dahlgren et al., 2004; Hiradate et al., 2004; Parfitt, 2009). These features arise from the presence of labile and active metals, chiefly Al and Fe, which are able to bind with humic substances to form nanoparticles of Al- and Fe-humic acid complexes that are very resistant to degradation or leaching (Hiradate et al., 2004; Basile-Doelsch et al., 2005). As well as strong bonding, the metal-humic acid complexes are also evidently protected by Al toxicity to microorganisms or enzymes, physical encasement within abundant micropeds, and a P deficiency of microorganisms arising from high P retention (Ugolini and Dahlgren, 2002; Parfitt, 2009). The resultant very dark or black melanic epipedons can contain as much as 25%–30% organic carbon (Drijber and Lowe, 1990; Nanzyo, 2002; Hiradate et al., 2004).

Most Xerands, such as those in central Washington, Oregon, and northern California, have formed under mixed vegetation of grass and forest whereas those in South Australia formed under dense to semi-open woodland and grassland/shrubland or fernland (Ping, 2000; Lowe and Palmer, 2005; Takesako et al., 2010). Torrands formed under shrubby or grass vegetation, and Vitrands under grass or forest in North America and Mexico and under broadleaf–podocarp forest in New Zealand. Cryands generally formed under forest, but in Iceland and other high-latitude polar regions including the Aleutians, these soils formed under tundra or moss, heath, grass, and "desert" covers (Arnalds et al., 1995; Ping, 2000; Arnalds and Kimble, 2001). In the tropics, the vegetation is often rain forest, particularly on the slopes of volcanoes where grassland and savanna types also occur.

Some black A horizons on Andisols in New Zealand, typically ≤20 cm thick, have been attributed largely to the effects of bracken fern (*Pteridium* spp.), which replaced much of the original forest after human-induced deforestation by Polynesian burning from about AD 1300 (Newnham et al., 1999; McGlone et al., 2005; Lowe, 2008). In northern Idaho, establishment of bracken fern following forest canopy removal is associated with decadal-scale changes in soil properties. These include increased soil C, darker soil colors, lower pH, and increased organic forms of active Al (Johnson-Maynard et al., 1997).

33.3.5.5 Time

Andisols generally are found on relatively young parent materials in humid climates because, on older and more stable landscapes, more weathering would normally have taken place resulting in the transformation to other soil orders such as Ultisols or Oxisols. The drier and cooler the environment, the longer it usually takes for an Andisol to form (Shoji et al., 2006). Tephras or volcanic materials, either very young or in extremely dry areas, and not sufficiently weathered to form the minimum requirements for andic soil materials, are placed in the Entisol order. An A horizon can form in newly deposited tephra in a few hundred years or so whereas the development of BC and then Bw horizons beneath, it may take several hundreds to several thousands of years according to environmental conditions and the nature of the tephra (Shoji et al., 1993; Ping, 2000; Lowe and Palmer, 2005; Lowe, 2008). However, in northeast Kodiak Island, Alaska, a Cryand formed on tephra erupted in the 1912 Mount Katmai event already has thin E and Bw horizons (Ping, 2000), and soils on young basaltic tephra surfaces in Iceland (<100 years) are classified as Andisols (Arnalds and Kimble, 2001).

In situations where just a single eruption event has taken place to produce a parent deposit, then Andisols developed in that material have the same age as the eruption. However, where Andisols comprise upbuilding sequences of tephras and soil horizons (as commonly occurs), the maximum age of the soil-profile constituents depends on the depth at which the profile "base" is drawn. In considering the uppermost 1–2 m of Andisols, some generalizations about their *composite* ages can be made. For example, in Japan, many Andisols are ~5,000–10,000 cal years old although some are considerably older (~25,000 cal years old; Takesako and Muranaka, 2006). In southeast Alaska, Cryands may be up to ~15,000 cal years old (Ping, 2000). In Iceland, most of the Andisols range in age from a few decades to ~10,000 cal years old (Arnalds et al., 1995). In New Zealand, there is a much wider range of ages on Andisols. Most of the Vitrands are ~700 years old (on rhyolitic Kaharoa Tephra) and ~1,800 years old (on rhyolitic Taupo Tephra); extensive Udands date back ~20,000–25,000 cal years and some are as old as ~60,000 years. In all these countries and others, tephrochronology—the identification and correlation of tephras and their application as a linking and dating tool (Alloway et al., 2007; Lowe, 2011)—has been used to provide age models for the Andisols. These age models rely mainly on radiocarbon and other techniques including dendrochronology and depositional age-depth modeling as well as wiggle-match dating (Lowe, 2011). Historical accounts provide ages for the youngest tephras (Alloway et al., 2007).

33.3.6 Pedogenic Processes in Andisols

The importance of upbuilding and polygenesis in the formation of Andisols has already been described. In this section, the collective process of andisolization in tephra materials with a significant content of volcanic glass is outlined. Andisolization leads to the formation of a fine colloidal fraction dominated by nanoscale minerals, notably allophane, ferrihydrite, and metal–humus complexes, with typically subordinate amounts of imogolite. Nanoscale minerals are defined as having at least one dimension in the nanorange, which is 1–100 nm (Hochella, 2008). These nanoscale minerals are composed of active forms of Al, Si, Fe, and humus and impart andic soil properties (Theng and Yuan, 2008). Although volcanic glass is a common

component in many Andisols, it is not a requirement of the Andisol order and some soils develop andic properties without the influence of glass (Soil Survey Staff, 1999). Soil solution and micromorphological studies show that, in contrast to podzolization, translocation of Al, Fe, organic matter, and clays is normally minimal in Andisols (Jongmans et al., 1994; Soil Survey Staff, 1999; Ugolini and Dahlgren, 2002; Stoops, 2007).

Allophane and imogolite (both aluminosilicates) and ferrihydrite (an iron hydroxide) are formed by the synthesis of soluble Al, Si, or Fe that are released from glass or other minerals (mainly feldspars or various mafic minerals) via rapid dissolution and hydrolysis by carbonic acid (H_2CO_3) normally under moderately acid and humid conditions. As soil solutions become rapidly oversaturated with respect to these nanominerals, they are precipitated preferentially because their nucleation is kinetically favored over that of less-soluble, long-range-order (crystalline) phases (Ugolini and Dahlgren, 2002; Theng and Yuan, 2008). Thermodynamic stability diagrams show that imogolite and very likely Al-rich allophane are more stable than halloysite over a wide range of Si activity, with the latter more stable than both imogolite and Al-rich allophane only at high Si activity (Farmer et al., 1991; Lowe and Percival, 1993; Hodder et al., 1996; Harsh, 2000). The central role of the Si leaching model in helping govern Si activity (i.e., concentration of $Si(OH)_4$ or monosilicic acid) was discussed earlier. Al-rich allophane forms at pH values between ~5 and 7, a value of at least ~4.8 being required for it to precipitate (Lowe, 1995; Dahlgren et al., 2004). Al undergoes hydrolysis and polymerizes in gibbsite-like octahedral sheets as $(OH)_3Al_2$ and

then combines with Si in tetrahedral coordination as O_3SiOH to form imogolite or allophane (Figure 33.19; Hiradate and Wada, 2005; Theng and Yuan, 2008). Allophane can form rapidly and has been observed to precipitate in a few months on the face of open soil pits containing rhyolitic tephra (Parfitt, 2009).

Note that a long-standing previous model in which allophane was suggested to weather or "crystallize" by solid-state transformation to form halloysite with time (because the latter often occurs in older, that is, deeper, tephras and associated soil horizons) has been largely discounted and replaced by this Si leaching model and its variants. For allophane to alter to halloysite requires a complete rearrangement of the atomic structures, and this could only occur by dissolution and reprecipitation processes because the allophane would need to "turn inside out" so that Si-tetrahedra are on the outside, not inside, the curved Al-octahedral sheets (Figure 33.21; Parfitt et al., 1983; Ildefonse et al., 1994; Lowe, 1995; Churchman, 2000; Hiradate and Wada, 2005; Parfitt, 2009). The effect of time is clearly subordinate because glass can weather directly via dissolution either to allophane or halloysite depending on glass composition and both macro- and microenvironmental conditions, not time (Lowe and Percival, 1993; Lowe, 1995; Parfitt, 2009). As well, allophane can persist for hundreds of thousands of years under favorable conditions (Stevens and Vucetich, 1985; Churchman and Lowe, 2011, Section 20.1).

The formation of ferrihydrite in Andisols and other soils has been described in a number of papers including Schwertmann and Taylor (1989), Childs (1992), Lowe and Percival (1993),
FIGURE 33.21 Diagram of imogolite tubes and allophane spherules. "Proto-imogolite" fragments have an imogolite atomic structure over a short range and link to form porous, hollow nanospheres with water molecules occupying the intra-spherule interior as well as being adsorbed to the outer AlOH surface (Parfitt, 2009). (After Lowe, D.J. 1995. Teaching clays: From ashes to allophane, p. 19–23. *In* G.J. Churchman, R.W. Fitzpatrick, and R.A. Eggleton (eds.) Clays: Controlling the environment. CSIRO Publishing, Melbourne, Australia.)

Churchman (2000), Bigham et al. (2002), Nanzyo (2002), and Dahlgren et al. (2004). After release of structural Fe from mafic primary minerals such as pyroxenes, amphiboles, biotite, and olivine (and presumably also from glass), Fe^{2+}-containing soil water oxidizes relatively quickly to Fe^{3+}, which immediately hydrolyzes to ferrihydrite. This occurs in the presence of organic matter, silicate, or phosphate, all of which inhibit the formation of more thermodynamically stable crystalline iron oxides. Ferrihydrite can redissolve readily by reduction (Schwertmann, 2008).

The availability of Al^{3+} is the critical factor regulating the formation of nonallophanic Andisols, which form preferentially in environments rich in organic matter and with pHs of ~5 or less, and which typically contain 2:1 layer silicate clays (Shoji et al., 1985, 1993; Nanzyo, 2002; Ugolini and Dahlgren, 2002; Dahlgren et al., 2004). At these pHs, organic acids are the dominant proton donors lowering pH and aqueous Al^{3+} activities through the formation of Al–humus complexes (also Fe–humus complexes, but less commonly). Under these conditions, carboxyl groups of humus and the 2:1 layer silicates (derived mainly from windblown dust) effectively compete for dissolved Al, leaving little Al available for coprecipitation with Si to form allophane or imogolite (Mizota and van Reeuwijk, 1989; Dahlgren et al., 2004). The preferential incorporation of Al into Al–humus complexes (and hydroxyl-Al interlayers of 2:1 layer silicates) has been termed the *antiallophanic* effect (Shoji et al., 1993). In Japan, allophanic Andisols tend to be formed where parent tephras are more basic (basaltic to andesitic) and rainfall is <1000 mm per year, so that higher pH values (>5) are favored (Dahlgren et al., 2004). Their distribution pattern is also attributed in part to proximity to volcanoes and the frequency therefore of tephra accretion vs. exotic dust accession (Saigusa and Matsuyama, 2004): sites closer to volcanoes effectively received a "top up" of Al through more regular deposition of weatherable tephras (resulting in allophanic Andisols) than at distal sites where the Al became quickly depleted (resulting in nonallophanic Andisols) through both humus complexing and "dilution" from the ongoing fallout of 2:1 mineral-bearing dust blown from China.

Changes in elemental composition during andisolization in Japan were studied by Nanzyo and Takahashi (2005).

33.3.7 Management of Andisols

Andisols support a much greater population than their limited extent would suggest. One reason for this is that crop productivity on Andisols is very high due to good physical properties and relatively high native fertility in some locations. Periodic additions of fresh tephra, especially when intermediate to basic in composition, can resupply potential nutrients and maintain favorable fertility levels in areas where other soils tend to be depleted in nutrients. For example, a "dusting" of andesitic ash fallout from the 1995–1996 Mt. Ruapehu eruptions in New Zealand added between 30 and 1500 kg ha^{-1} of sulfur as well as small quantities of Se, Mg, and K to substantial land areas (Lowe and Palmer, 2005). Consequently, in many areas, few inputs with the exception of P have been required for successful agricultural production on many Andisols. Andisols are also productive forest soils. In the Pacific Northwest region of United States, the presence of tephra (ash) mantles and their water-holding capacity is closely linked to forest productivity (Kimsey et al., 2008). Vitrands in New Zealand also support very productive plantation forestry (Ross et al., 2009).

Nevertheless, in other locations such as New Zealand where rainfall and leaching are generally high, and where siliceous tephras low in metals are common, many Andisols have low fertility because of a range of chemical limitations both acquired and inherited. As well as P fixation, exchangeable bases (especially K) tend to be low and other elemental deficiencies may include Mg, S, Co, and others (Lowe and Palmer, 2005). The high productivity of these soils is thus maintained by regular fertilizer input in combination with their generally excellent physical properties.

Most Andisols are acid and where acidity is particularly high, high levels of exchangeable Al may inhibit crop growth (Al toxicity). This is especially a problem in nonallophanic Andisols (Shoji et al., 1993; Shoji and Takahashi, 2002; Dahlgren et al., 2004). In such instances, addition of lime can reduce the amounts of organically complexed Al and exchangeable Al (Takahashi et al., 2006), or acid-tolerant crops must be selected (Michaelson and Ping, 1987; Nanzyo, 2002; Shoji and Takahashi, 2002). Where Andisols have been acidified by long-term N inputs, serious consequences for crop production can arise because as pH decreases, CEC also decreases. As a result, such soils are able to hold few base cations (Ca, Mg, and K) for plant uptake (Sumner and Hylton, 1993).

Requirements for N vary according to the ease with which organic matter is mineralized in these soils. Nitrogen mineralization is slower in allophanic Andisols than in nonallophanic Andisols because organic matter interacts with and is stabilized by allophane in the former (Parfitt, 2009). Liming often promotes the release of substantial amounts of N from nonavailable reserves, thereby improving N fertility.

As noted above, the high P-fixing capacities of most Andisols necessitate inputs of P for successful agricultural production (Michaelson and Ping, 1990; Dahlgren et al., 2004; Lowe and Palmer, 2005). Such inputs in the form of rock phosphate are effective on very acid Andisols but in any event, soluble P sources should be band-placed or otherwise protected from intimate mixing with the soil (Sumner and Hylton, 1993).

Other nutrients may sometimes be deficient in Andisols depending of the chemical composition of the parent material. One notable example occurs in the central North Island of New Zealand where Vitrands, formed in the silica-rich Taupo and Kaharoa tephras, are deficient in micronutrients including Co, Se, Cu, B, I, and Mo. Inherently low Co in these pumiceous parent tephras led to low Co levels in soils and herbage, and ultimately to a deficiency in ruminant animals (sheep and cows)

that developed a serious and commonly fatal wasting disease known as "bush sickness" (Lowe and Palmer, 2005; Neall, 2006). This term referred to a variety of symptoms exhibited by livestock stemming from their inability to produce vitamin B12, of which Co is an essential component (Cornforth, 1998). The association of this condition with the Vitrands was recognized in the early 1930s (Grange and Taylor, 1932), and the cause identified a few years later. Acquired Co deficiency also occurred in some Udands and non-Andisol orders where high rainfall and strong leaching were the cause. Subsequent use of cobaltized superphosphate, and other methods, corrected the problem (Neall, 2006).

Andisols, in general, are noted for their good physical properties including high water-holding capacity, free drainage, good tilth and friability, resistance to water erosion, stable aggregation, low bulk density and high porosity, and hence good aeration. Consequently, they are usually excellent media for seedling emergence and root growth and proliferation. It should be emphasized that these properties can and often are altered through management (e.g., Candan and Broquen, 2009). Where uncultivated, undisturbed Andisols may be resistant to erosion, but loss of vegetative cover, compaction, and subsequent reduction in infiltration can lead to severe runoff and erosion including deep gullying in Vitrands (Lowe and Palmer, 2005). Agricultural production on Andisols can result in erosion and compaction, and no-till or reduced tillage farming practices are recommended to minimize these problems in agricultural systems (Dahlgren et al., 2004). Heavy livestock grazing can also compact Andisols (Schlichting, 1988). In the Pacific Northwest of United States, compaction resulting from mechanized timber harvesting can reduce infiltration and water-holding capacity of Andisols (Cullen et al., 1991). Severe erosion from harvested sites can also significantly reduce water-holding capacity to the point where site productivity is drastically diminished (McDaniel et al., 2005). In Iceland, Cryands have been overgrazed, denuded, and subject to severe wind erosion (Arnalds et al., 1995; Arnalds and Kimble, 2001).

As noted earlier, properties of sensitivity and thixotropy can cause Andisols to behave in a fluid-like manner when loading pressures are applied. Thus, Andisols are susceptible to failure when disturbed on slopes, which can cause them to reach the liquid limit, generating landslides (Basile et al., 2003; Neall, 2006). Mantling of harder bedrock by andic soils and the layering associated with tephra deposits and buried soils can form planes of failures (Arnalds, 2008).

Because of their sorptive capacity for anions and metals, Andisols offer potential environmental benefits as active filters. High nitrate adsorption by allophanic Andisols was correlated with retarded nitrate transport rates under coffee plantations in Costa Rica (Reynolds-Vargas et al., 1994; Ryan et al., 2001). Reduced phosphorus leaching losses from surface-applied domestic effluent in New Zealand have been attributed the relatively high P sorption capacity of Andisols (Barton et al., 2005). Similarly, the sorption of arsenate by Andisols offers potential for purifying drinking water or for remediating As-contaminated soils (Arai et al., 2005; Theng and Yuan, 2008). McLeod et al. (2008) have also demonstrated that New Zealand Andisols leached very small amounts of surface-applied microbial tracers via bypass flow, attributable to their sorptive capacity and the fine, porous nature of the soils. These and other studies suggest that Andisols may play an important role in reducing groundwater contamination.

33.4.1 Introduction

Entisols are mineral soils that commonly exhibit minimal pedogenic alteration (Soil Survey Staff, 1999, 2010). This taxonomic order was established to preserve the early Russian "azonal" concept for soils with undeveloped profiles crossing bioclimatic zones (Smith, 1986). Typically described as A-C, A-Cr, or A-R profiles, Entisols retain many physical and chemical properties of the associated parent materials. Most A horizons classify as ochric epipedons, but with Ap horizons classifying as anthropic in some human-disturbed lands and as agric in some agricultural lands. Occasionally, Entisols have histic epipedons if affiliated with sulfidic materials in coastal regions with persistently high water tables. Highly disturbed soils from human activity may have fragments of former diagnostic horizons classified as Entisols.

Subsurface B horizons may be described to indicate a pathway of pedogenesis (e.g., Bw), but the properties must not meet the minimum requirements of any subsurface diagnostic horizon (e.g., cambic). Exceptions are the recognition of a weathered albic horizon as long as genetically related illuvial horizons (e.g., argillic and spodic) do not occur within 2 m of the surface, and cryoturbation in Gelisols that prevents diagnostic horizons from forming. Despite minimal horizonation, however, Entisols must develop physical and chemical properties capable of supporting plants. This characteristic distinguishes Entisols from nonsoil areas such as rock outcrop, water, ice, or badlands.

33.4.2 Distribution

Entisols most often occur where the influence of the soil-forming factors retards pedogenesis. Landforms where Entisols form are marshes and estuaries, modified urban areas, sand dunes, floodplains, and arid regions with steep or rocky slopes (Figure 33.22). These landforms are associated with wetlands, inert sandy parent materials, rapid rates of aggradation or erosion, and intensive human activity (Buol et al., 1997). Because of the geographic extent of these environments, Entisols are the most abundant of all soil orders covering approximately 16% of the world's ice-free land mass (Soil Survey Staff, 1998). Up to 60% of Entisols occur in temperate and tropical regions, and many mapped in circumarctic regions have been replaced by the Gelisol order.

Entisols are replete in buried contexts throughout the Phanerozoic (see Birkeland, 1999). Recognition of Entisols is important for understanding Quaternary landscape evolution and preservation potentials of the buried archaeological record (Holliday, 2004). Paleo-Entisols in the pre-Quaternary rock record serve as sequence stratigraphic markers (McCarthy and Plint, 1998; Atchley et al., 2004), enhance interpretations of pedofacies relations (Kraus, 2002), provide inferences regarding colonizing ecosystems (Retallack, 1994), and serve as repositories of paleobotanical and paleontological information (see Retallack, 2001).

33.4.3 Formation

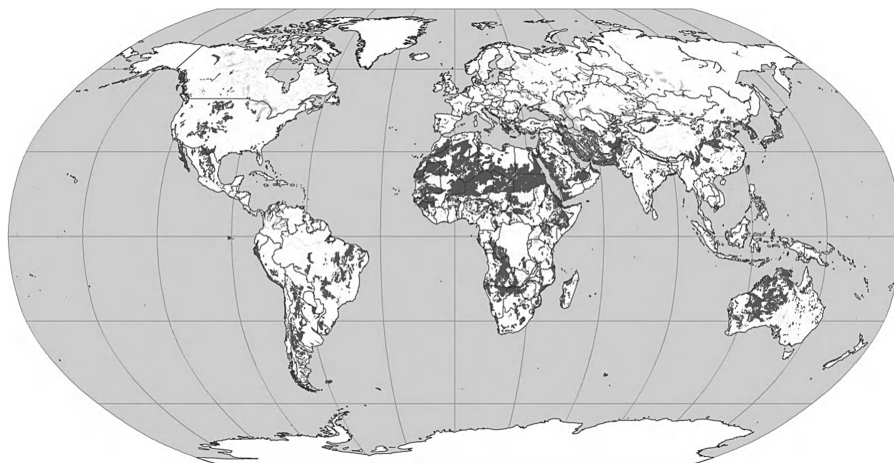
Ripening and melanization are the principle soil-forming processes that initiate the development of surface diagnostic horizons and Entisols (Buol et al., 1997). Grossman (1983) reports data showing that bulk densities in alluvial settings initially increase because of frequent wetting and drying cycles, which leads to compaction. This process is similar to ripening as freshly deposited sediments from running water become dehydrated, but is followed by ped formation and increased porosity (Pons and van der Molen, 1973). Melanization contributes organic materials to the parent material by way of plant and animal activity promoting structural development that is accompanied by increased porosity and minor release


FIGURE 33.22 Global distribution of Entisols. (Courtesy of USDA-NRCS, Soil Survey Division, World Soil Resources, Washington, DC, 2010.)
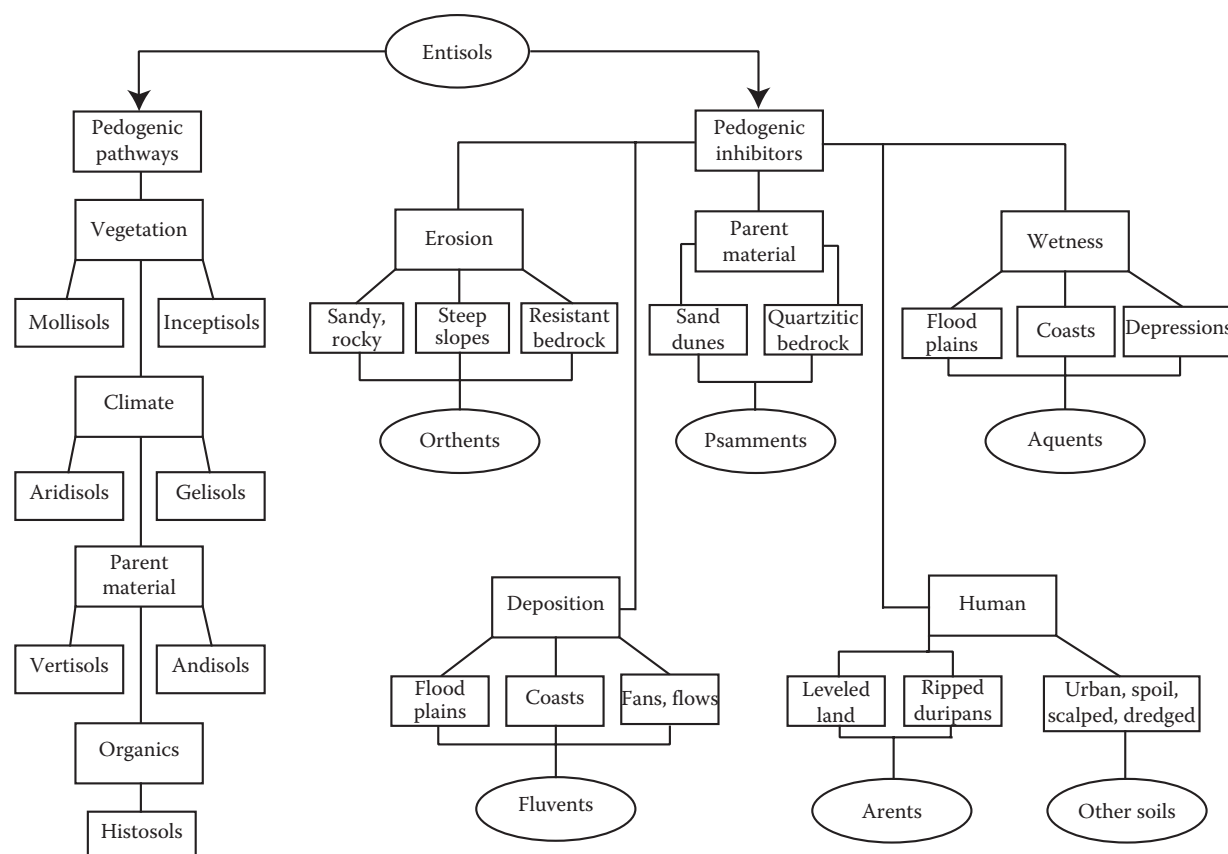

FIGURE 33.23 Flow diagram illustrating pedogenic pathways of Entisols to other soil orders and pedogenic inhibitors conditioning the formation of Entisol suborders.

and leaching of soluble constituents. In resistant bedrock, this process increases porosity as rock material is weathered and replaced by organic material. The processes of ripening and melanization in the formation of Entisols can proceed as long as mollic or umbric epipedons or subsurface diagnostic horizons do not form.

Entisols serve as the precursor to all other soil orders during their evolutionary history (Figure 33.23) (Soil Survey Staff, 1999, 2010). In grasslands, Mollisols with mollic epipedons form from Entisols when steady state has been attained in the accumulation of organic matter. In forest settings, ochric epipedons and Inceptisols may form because of relatively low, subsurface biomass production. Entisols develop into Aridisols outside of floodplains in areas with aridic soil moisture regimes. Vertisols form from Entisols in shrink-swell parent materials where wet–dry cycles are prevalent, and Andisols form from Entisols in parent materials with large quantities of volcanic ash in cool and humid climates. Histosols may form from Entisols with the accumulation of significant amounts of organic matter in association with high water tables and anaerobic conditions.

33.4.4 Suborders

In contrast to most other soil orders, suborders of Entisols are not defined by precipitation or temperature regime. Rather, Entisol suborders are designed primarily to differentiate conditions

that impede subsurface horizon development (Smith, 1986; Soil Survey Staff, 1999, 2010). The five Entisol suborders are Aquents, Arents, Psamments, Fluvents, and Orthents (Figures 33.23 and 33.24). The great group and subgroup lower taxonomic levels recognize extragrades and intergrades to other soil moisture regimes and diagnostic conditions (Table 33.18).

33.4.4.1 Aquents

Aquents are wet Entisols. They exist widely in the United States, except in Arizona and New Mexico, with the largest concentrations in southern Florida (Soil Survey Staff, 1990). Worldwide, Aquents are not extensive, covering approximately 0.1% of the Earth's land. Areas where Aquents occur include salt marshes of coastal tidal areas, freshwater marshes and swamps, alluvial flats and backswamps of floodplains, and outwash plains that receive new deposits of sediment at frequent intervals. Depending on where Aquents are located, some can be used for agricultural production when drained. Many undrained areas of Aquents are used for pasture or wildlife habitat.

Aquents are defined as having aquic conditions and sulfidic materials within 50 cm of the mineral soil surface, or permanent saturation and a reduced matrix below a depth of 25 cm from the mineral soil surface, or texture and color requirements if a densic, lithic, or a paralithic contact, or the presence of aquic conditions for some time in some years in a layer between 40 and 50 cm from the
FIGURE 33.24 Block diagram illustrating typical landscape positions where Entisol suborders form: Orthents on steep slopes associated with bedrock, Fluvents in floodplains that include postsettlement alluvium, Aquents in poorly drained riparian conditions, and Psamments in sand dunes. Arents not shown.

mineral soil surface (Soil Survey Staff, 1998). Aquents can range in texture from sandy to clayey. One common feature of all Aquents is their saturation with water at or near the surface for much of the year, which presents many engineering and land use challenges.

Wetness in Aquents is normally inferred by the color distribution generated by the redox state of Fe. In most Aquents, this process produces redoximorphic features (Fe concentrations or depletions) within the upper 50 cm of the surface. Redoximorphic features are most common in nonsandy Aquents. The sandy Aquents (Psammaquents) often lack redoximorphic features because of the very low Fe content of the quartz-rich parent materials. Many Aquents have hydric soil indicators (thin layer of muck on the soil surface, strong sulfidic odor, or a gray and reduced soil matrix in the upper 15 cm of the soil; USDA-NRCS, 1996). Florida law and county listings elsewhere show that some Aquents (Sulfaquents, Hydraquents, and Psammaquents) are considered as hydric soils (Florida Statutes, 1995).

33.4.4.1.1 Lower Taxonomic Levels

Aquents are associated with landscapes that accumulate soil water. They exist in cryic to isohyperthermic soil temperature regimes. Sulfaquents and Hydraquents are located along coastal areas in

TABLE 33.18 Listing of Suborder, Great Groups, and Subgroups in the Entisol Order

Suborder	Great Group	Subgroup
Aquents	Sulfaquents	Haplic, Histic, Thapto-Histic, Typic
	Hydraquents	Sulfic, Sodic, Thaptic-Histic, Typic
	Cryaquents	Aquandic, Typic
	Psammaquents	Lithic, Sodic, Spodic, Humaqueptic, Mollic, Typic
	Fluvaquents	Sulfic, Vertic, Thapto-Histic, Aquandic, Aerie, Humaqueptic, Rhodic, Mollic, Typic
	Epiaquents	Aerie, Humaqueptic, Mollic, Typic
	Endoaquents	Sulfic, Lithic, Sodic, Aerie, Humaqueptic, Mollic, Typic
Arents	Ustarents	Haplic
	Xerarents	Sodic, Duric, Alfic, Haplic
	Torriarents	Sodic, Duric, Haplic
	Udarents	Alfic, Ultic, Mollic, Haplic
Psamments	Cryopsamments	Lithic, Aquic, Oxyaquic, Vitrandic, Spodic, Lamellic, Typic
	Torripsamments	Lithic, Vitrandic, Haploduridic, Ustic, Xeric, Rhodic, Typic
	Quartzipsamments	Lithic, Aquodic, Aquic, Oxyaquic, Ustoxic, Udoxic, Plinthic, Lamellic Ustic, Lamellic, Ustic, Xeric, Spodic, Typic
	Ustipsamments	Lithic, Aquic, Oxyaquic, Aridic, Lamellic, Rhodic, Typic
	Xeropsamments	Lithic, Aquic Durinodic, Aquic, Oxyaquic, Vitrandic, Durinodic, Lamellic, Dystric, Typic
	Udipsamments	Lithic, Aquic, Oxyaquic, Spodic, Lamellic, Plaggeptic, Typic
Fluvents	Cryofluvents	Andic, Vitrandic, Aquic, Oxyaquic, Mollic, Typic
	Xerofluvents	Vertic, Aquandic, Andic, Vitrandic, Aquic, Oxyaquic, Durinodic, Mollic, Typic
	Ustifluvents	Aquertic, Torrertic, Vertic, Anthraquic, Aquic, Oxyaquic, Aridic, Udic, Mollic, Typic
	Torrifluvents	Ustertic, Vertic, Vitrixerandic, Vitrandic, Aquic, Oxyaquic, Duric Xeric, Duric, Ustic, X, Anthropic, Typic
	Udifluvents	Aquertic, Vertic, Andic, Vitrandic, Aquic, Oxyaquic, Mollic, Typic
Orthents	Cryorthents	Lithic, Vitrandic, Aquic, Oxyaquic, Lamellic, Typic
	Torriorthents	Lithic Ustic, Lithic Xeric, Lithic, Xerertic, Ustertic, Vertic, Vitrandic, Aquic, Oxyaquic, Duric, Ustic, Xeric, Typic
	Xerorthents	Lithic, Vitrandic, Aquic, Oxyaquic, Durinodic, Dystric, Typic
	Ustorthents	Aridic Lithic, Lithic, Torrertic, Vertic, Anthraquic, Aquic, Oxyaquic, Durinodic, Vitritorrandic, Vitrandic, Aridic, Udic, Vermic, Typic
	Udorthents	Lithic, Vitrandic, Aquic, Oxyaquic, Vermic, Typic

tidal marshes. Sulfaquents, as the name implies, have sulfidic materials. Hydraquents are thixotropic soils, meaning that they cannot support appreciable overburden pressures (n value >0.7). Psammaquents have a texture of loamy fine sand or coarser in all layers within the control section for the family particle size class. Fluvaquents occur on floodplains and are defined by the amount of organic C and its distribution in the soil. Cryaquents form in the colder climatic areas of Alaska and other higher latitudes that receive significant snowfalls, and soil development is slow.

33.4.4.1.2 Genesis

In association with wet conditions, Aquents form where pedogenetic development does not occur or is very slow. The soil must be saturated for long periods, and in some areas, organic matter can accumulate to create a histic epipedon. Saturation in Aquents can be episaturated (perched water table) or endosaturated (apparent water table). The time needed for Aquents to develop can be short. On floodplains and other areas experiencing rapid deposition, Aquents commonly have stratified layers of sand, silt, clay, and organic matter. Aquents forming on floodplains may also have buried histic epipedons. Aquents with high clay content may have vertic properties.

Aquents from Florida (Pellicer series: fine, smectitic, nonacid, hyperthermic Typic Sulfaquents), Egypt (Edko series: fine-loamy, mixed, nonacid, hyperthermic Mollic Fluvaquents), and Alaska (Beluga series: coarse-loamy, mixed, superactive, nonacid, Typic Cryaquents) are selected to represent Aquents from different geographic areas and to reflect different genetic pathways. The Pellicer soils form in clayey marine sediments in tidal marshes along the Atlantic coastal areas of Florida (Carlisle et al., 1981). These soils are very poorly drained and subject to daily tidal flooding. The representative Aquent from Egypt has anthric saturation and redoximorphic features in the form of brownish Fe accumulations. The soil was sampled in a depressional area south of Lake Burullus near Resheed City in northern Egypt (Rasheed et al., 1992). The Edko soil developed in recent fluviolacustrine deposits in an aridic climate. The Beluga soils are extensive on floodplains and alluvial fans in southern Alaska and form in stratified alluvium and colluvium derived from soft clayey shale and sandstone. These soils are poorly drained and saturated with water at the surface for portions of the year.

33.4.4.1.3 Physical and Chemical Properties

Physical properties such as particle size distribution and chemical properties such as organic C content, pH, extractable bases, and CEC_7 are presented for the Pellicer and Edko soils (Table 33.19). The sand, silt, and clay content of the Pellicer varies considerably within the profile, reflecting the different conditions under which the materials were deposited. Organic C content of this soil is high in the surface horizon as a result of the accumulation of organic materials under wet conditions. The Pellicer soils are high in S content (1%–4%), and this is reflected in the extremely low pH values (<3.5).

The sand, silt, and clay content of the Edko soil is fairly evenly distributed through the profile. In contrast to the Pellicer soils, the pH of the Edko soil is high (≥8.4) due to the high Na content.

33.4.4.1.4 Subaqueous Soils

An amendment to *Soil Taxonomy* to better classify subaqueous soils has been developed by Dr. Mark Stolt, Professor of Pedology at the University of Rhode Island (Soil Survey Staff, 2010). The formative element Wass is derived from the German (Swiss) word "wasser" for water and is used for subaqueous Histosols and Entisols. Six great groups within Wassents are proposed keying out in the order: Frasiwassents, Psammowassents, Sulfiwassents, Hydrowassents, Fluviwassents, and Haplowassents. The depth range of the water column where these soils occur is not known but a depth of 2.5 m below the surface has been set for soil survey inventory. Excluded are soils in areas where the water column is too thick (>2.5 m) for the growth of rooted plants. Subaqueous soils occur in protected estuarine coves, bays, inlets, and lagoons.

Only recently have pedologists considered these substrates to be soil material. Consequently, very few subaqueous soils have been characterized, and relationships between subaqueous soils and associated subtidal landforms have not been extensively studied. Recent subaqueous soil projects have been undertaken or are in progress along the Gulf coast in Florida and Texas and the Atlantic Coast in Connecticut, Delaware, Florida, Maine, Maryland, Massachusetts, New Hampshire, and Rhode Island. Work along the southeast Atlantic Coast of Florida (Fischler, 2006) has included mapping and classification of subaqueous soils near Cedar Key, Florida (Ellis, 2006), quantifying human activities that either destroy or create an environment in which it is difficult to reestablish the fragile seagrass vegetation, and studying the biogeochemical characteristics of subaqueous soils as related to aquatic vegetation in a river flowing into the Gulf of Mexico (Saunders, 2007).

33.4.4.2 Arents

Arents are former soils physically disturbed by the actions of humans (Soil Survey Staff, 1999, 2010). Arents are restricted to those soils "which have, in one or more layers between 25 and 100 cm from the mineral soil surface, 3% or more by volume fragments of diagnostic horizons that are not arranged in any discernible order (Soil Survey Staff, 1999, 2010)." Two examples of the transformation of preexisting soils into Arents follow.

Duripans were ripped by heavy equipment to improve the soils for the growth of almond nut trees in California (R.W. Simonson, personal communication, based on observations in the 1960s). According to Dr. Simonson, the ripping was possible only with moderately developed duripans, whereas thick, strongly developed duripans were impossible to rip. The value of the land was greatly improved by the ripping, such that successful commercial almond production became possible. As a result of the duripan ripping, the great group classification of the soils changed from Durixeralfs to Xerarents.

Another example of Arent soil formation occurred in western Tennessee where formerly gullied land was leveled with heavy equipment for agricultural purposes. Fragments of argillic horizons from the original Alfisols permitted the new soils to be identified as Arents after the land disturbance. Thus, Hapludalfs (i.e., Memphis soil series) were reclassified to Udarents following the leveling.

TABLE 33.19 Soil Characterization Data for the Pellicer Clay (Carlisle et al., 1981) and Edko Soil (Rasheed et al., 1992) of the Aquent Suborder

Horizon	Depth (cm)	Very Coarse Sand	Coarse Sand	Medium Sand	Fine Sand	Very Fine Sand	Silt	Clay	pH (H$_2$O)	OC[a] (%)	Ca[b]	Mg	Na	K	CEC$_7$	Base Saturation (%)

33.4.4.2.1 Soils in Human-Deposited or Human-Exposed Parent Materials

Humans affect soils in many ways. These soils form in mine spoil, dredge spoil, and other recently deposited urban and industrially related materials, as well as in bomb craters in war zones (Hupy and Schaetzl, 2006). Some Entisols have been brought into existence where humans have deposited or exposed soil parent material by earth-moving operations. Some of these operations include highway construction, surface mining, landfill construction, or dredging.

In many soils with human-deposited or human-exposed parent materials, fragments of diagnostic horizons are not identifiable; thus, a classification of Arents would not be appropriate. Such soils commonly have been classified in the suborder of Orthents and subdivided into great groups according to the soil moisture regime (i.e., into Udorthents in the eastern United States; Soil Survey Staff, 1999, 2010). This classification is insufficient for many soil scientists because it does not reflect the role of humans in the genesis of the soils (Short et al., 1986a; Strain and Evans, 1994). Although these soils are commonly thought to be highly variable, studies have shown degrees of variability similar to that of some soils in naturally deposited parent materials (Short et al., 1986b).

Many soils forming in materials deposited by bulldozers or other earth-moving equipment have an irregular distribution of organic matter with depth. In theory, these soils would classify as Fluvents at the suborder taxonomic level (Soil Survey Staff, 1999, 2010). In contrast to Fluvents, however, human-disturbed soils are not stratified by natural processes, are not flooded in most years, and have a higher density. Despite the irregular organic matter depth distribution, these soils behave more like Orthents than Fluvents and have been forced, in some soil surveys (Smith, 1976), into Orthents by ignoring the irregular organic matter depth distribution.

Because of the inadequacies of the present classification system, new suborders and/or subgroups of Entisols have been proposed for soils in human-deposited or human-exposed parent materials (Fanning and Fanning, 1989; Chapters 24, 28, and Appendix 3). An international committee for anthropogenic soils (ICOMANTH) has shown considerable interest in adding new taxonomic classes. The committee, however, has not determined at which taxonomic level human-influenced soils should be recognized. For example, Kosse (1988) and Strain and Evans (1994) have proposed classifying these soils at the order level as Anthosols. Regardless, the Arent suborder discussed above established a precedence for recognition at the suborder level. Fanning and Fanning (1989) have supported this viewpoint.

West Virginia workers (Sencindiver, 1977; Smith and Sobek, 1978) proposed the suborder Spolents (for spoil) for soils formed in materials deposited from surface mining operations. During development of the soil survey of Washington, DC, Smith (1976) proposed a suborder of Urbents for soils formed in miscellaneous urban fill that had artifacts such as brick or concrete in the particle size control section (generally between a depth of 25 and 100 cm). The Garbents suborder was proposed for soils formed in garbage of an organic nature within a depth of 2 m from the soil surface, such that the soils would readily subside

and generate methane under anaerobic conditions (Fanning and Fanning, 1989; Fanning, 1991). Fanning and Fanning (1989, Chapter 24) proposed special diagnostic soil characteristics (i.e., urbic, garbic, spolic, and dredged material; and the scalped land surface) for taxonomic classification. These characteristics were employed to propose special subgroup classes, such as Urbic Garbic Udorthents for "sanitary landfills where the cover material qualified as urbic materials" (Fanning and Fanning, 1989, Appendix 3). It was proposed that soils on scalped land surfaces (cuts from an engineering perspective) could be placed in Scalpic subgroups.

Soils created by dredging operations commonly qualify as Sulfaquents immediately after sulfidic dredged materials have been deposited (Fanning and Fanning, 1989). Under aerobic conditions at dredged material sites, sulfuric horizons commonly form from sulfidic materials in a few weeks or months. This causes the soils to become Sulfaquepts, a great group of Inceptisols. Thus, the period that such soils remain as Entisols, before becoming a soil of a different order, may be very brief.

With the present strong interest in improving knowledge about the classification of human-influenced soils, much progress may be expected in the near future. This is needed as soil surveys of lands with human-influenced soils are becoming more widespread. In ongoing urban surveys, many of the problems associated with the soils discussed in this section will be encountered. For example, sulfide-bearing clays have been used as landfill cover materials, which can lead to the formation of acid sulfate soils on landfills (Kargbo et al., 1993; Fanning and Burch, 1997). A more resolved classification system can enhance future interpretations and mapping techniques of soil surveys in these areas. Further, it has been suggested (Fanning, 1990) that a discipline of pedotechnology is needed to improve the design of soils brought into existence through the action of humans.

33.4.4.3 Psamments

Psamments are Entisols with sandy parent materials. They typically show little or no evidence of soil development with horizon sequences of AC or A/AC-C. An exception, however, are areas (e.g., central Florida ridge) where Psamments represent intensely weathered albic horizons with argillic and spodic horizons forming at depths greater than 2 m below the surface. Consequently, Psamments generally have an ochric epipedon, but lack any diagnostic subsurface horizons within the upper 2 m depth.

Psamments cover 3.4% of the Earth's land. Major desert regions, such as in northern Africa (Sahara), Saudi Arabia, western Australia, and southern Mongolia (Gobi), have Psamments. In the United States, these soils exist in all states. They are extensive in the Central Ridge of Florida, in the Sandhills in western Nebraska, in the sandsheet in south Texas, in central Wisconsin, and throughout the arid and semiarid areas of the western United States on the leeward sides of pluvial lakes.

Generally, Psamments have low amounts of plant nutrients, low water-holding capacity, and rapid permeability. Irrigation is normally necessary to maintain economical crop production. With management, however, they can be used for citrus

production, for growing sand pines, and even for real estate development. In arid and semiarid regions, Psamments are ecologically fragile, and disturbance to rangeland vegetation growing on them can initiate feedback processes leading to severe desertification (Monger and Bestelmeyer, 2006).

Natural vegetation associated with Psamments in Florida consists of bluejack oak (*Quercus incana*), blackjack oak (*Quercus marilandica*), turkey oak (*Quercus laevis*), longleaf threeawn (*Aristida stricta*), and bluestem (*Andropogon* sp.). In the major cattle-growing states of Texas and Nebraska, Psamments are used for spring and summer grazing of native grasses. In central Wisconsin, truck crops are an important use.

33.4.4.3.1 Lower Taxonomic Levels

Psamments are restricted to soils that have a texture of loamy fine sand or coarser in the control section (family particle size class) and <35% by volume of particles >2 mm diameter (Soil Survey Staff, 1999, 2010). The latter distinguishes Psamments from sandy Orthents. Sandy loam lamellae are permitted in Psamments, as long as cumulatively they do not meet the requirements of an argillic horizon.

Psamments occur in a wide range of climates. Five of the six great groups reflect a climatic/geographic bias. Only Quartzipsamments do not indicate a geographic location, but rather the dominant mineralogy, quartz. Psamments exist in cryic or pergelic (Cryopsamments) soil temperature regimes but also are located in aridic (Torripsamments), ustic (Ustipsamments), xeric (Xeropsamments), and udic (Udipsamments) soil moisture regimes.

Subsurface features present in some Psamments include a lithic contact (Lithic), aquic or oxyaquic conditions, lamellae (Argic), plinthite, or durinodes. Thus, subsoil features vary greatly, and the variation is noted in the subgroup taxonomic name. Examples include Lithic Cryopsamments, Plinthic Quartzipsamments, and Aquic Durinodic Xeropsamments.

At the subgroup taxonomic level, climatic/geographic conditions are also described. As an example, Aridic Ustipsamments are located in several soil temperature regimes, but must have a period of time in which the soil is dry in all parts. The length of time that the soil must be dry is defined by the soil temperature regime.

33.4.4.3.2 Genesis

Genetically, Psamments develop in areas high in sand content (>85%). The parent material can be geologically young, as in eolian or alluvial materials or old, as in sandy residual bedrock. Sand dunes of either marine (Florida) or eolian (Saudia Arabia or Nebraska) origin are common parent materials. Some Psamments form in materials weathered from sandstone bedrock (e.g., South Dakota or Montana). Depending on the mineralogy of the sand, Psamments (Quartzipsamments) can be very resistant to weathering.

33.4.4.3.3 Representative Psamments

Psamments from Florida (Astatula series: hyperthermic, uncoated, Typic Quartzipsamments), Nebraska (Valentine series: mixed, mesic Typic Ustipsamments), and Saudi Arabia (Torripsamments) were selected to represent different geographic areas and, therefore, different genetic pathways. But morphologically, these soils are very similar and they are excessively drained.

Astatula, Valentine, and the Torripsamments from Saudi Arabia have thick C horizons with thin A horizons. If an A horizon is present, it is light colored and <15 cm thick. The A horizon is subject to continual mixing by wind action. Astatula soils form in eolian and marine sands and are extensive in peninsular Florida on upland slopes that range from 0% to 30%. Valentine soils form in sand dunes in the Sandhills of Nebraska on slopes that range from 0% to 60%. The sand dunes generally are oriented in a northwest to southeast direction (prevailing wind direction). In addition to Nebraska, Valentine soils occur extensively in Kansas, Montana, New Mexico, South Dakota, Texas, and Wyoming (>2 million ha). The Torripsamments from Saudi Arabia form in sand dunes and also in alluvial sandy deposits on plains and stream terraces. The dunes range in height from <2 to >10 m.

33.4.4.3.4 Physical and Chemical Properties of Representative Psamments

Physical and chemical properties are presented for the Astatula in Florida and for the Valentine in Nebraska (Table 33.20). Astatula soils (Quartzipsamments) have low organic C content and are strongly acid (pH < 5.5) and strongly leached as a consequence of high rainfall (1270 mm year^{-1}). Torripsamments from Saudi Arabia with <100 mm year^{-1} precipitation (data not shown have an accumulation of bases and are alkaline in reaction (pH > 8.5)). The sand size fraction of the Astatula and Valentine series are dominated by fine sand. Clay content of these Psamments is <5%.

33.4.4.4 Fluvents

Fluvents are Entisols that form in alluvium of rapidly aggrading floodplains, fans, deltas, and in some cases mudflows. World coverage of Fluvents is 2.2%, principally within major river valleys (see Lindbo, 1997).

When rates of deposition in alluvial settings approximate rates of pedogenesis, A-C soil profiles develop. In many instances, the A horizon is an ochric epipedon, but in others the surface horizon may be bedded (Soil Survey Staff, 1999, 2010). Alluvial processes prevent the formation of subsurface diagnostic horizons because of variations in flood magnitude and frequency leading to fluctuations in organic carbon content with depth. This occurs because greater quantities of allogenic organic matter tends to be associated with clayey rather than sandy flood deposits (Grossman, 1983). To taxonomically capture these conditions, organic carbon content in Fluvents must decrease irregularly with depth, or be above 0.2% at a depth of 125 cm.

Fluvents are differentiated from other Entisol suborders by (1) having textures finer than loamy very fine sand and less than 35% rock fragments (Psamments); (2) occurring on slopes less than 25% and without a densic, lithic, or paralithic contact within 25 cm (Orthents); (3) not having aquic conditions (Aquents); (4) having less than 3% fragments of diagnostic horizons in no discernable order (Arents); and (5) having any soil temperature regime that excludes the presence of gelic materials (Soil Survey Staff, 1999, 2010).

33.4.4.4.1 Other Taxonomic Levels

Great groups of the Fluvents are differentiated by either soil temperature or soil moisture regime (Soil Survey Staff, 1999, 2010). Fluvents occur in udic (Udifluvents), ustic (Ustifluvents), xeric (Xerofluvents), and aridic (Torrifluvents) moisture regimes (see Sidhu et al., 1994). They also occur in cryic temperature regimes (Cryofluvents) and in colder areas without permafrost (Gelifluvents). Fluvents form in all other soil temperature regimes (frigid, mesic, thermic, and hyperthermic), including those with minimal annual temperature change (iso).

At the subgroup taxonomic level, typical Entisols intergrade to the Andisol (andic), Mollisol (mollic), Aridisol (aridic), and Vertisol (vertic) orders, and to other soil moisture and temperature regimes not used at the great group categorical level. For additional information on the family taxonomic classification of Entisols, see the Soil Survey Staff (1999, 2010).

33.4.4.4.2 Climate, Vegetation, and Topography

Fluvents are soils in disequilibrium with the regional influence of climate, vegetation, and in some cases topography. Thus, Fluvents can occur in most climates associated with most vegetation communities and on a variety of alluvial slopes. Climate can, however, indirectly influence the chemical and physical properties of Fluvents. Alluvium transported into floodplains, fans, deltas, or mudflows is derived from erosion of soils within the surrounding drainage basin where properties are more likely to reflect regional climate conditions. These preconditioned sediments can expedite the transformation of Entisols to other soil orders.

Flood frequency and magnitude in many areas appear to be increasing because of urbanization and other changes in land use practices. Many workers have observed this hydrological phenomenon where Inceptisols, Mollisols, and Vertisols of inactive or slowly aggrading floodplains are being buried by Historic sediments coined "postsettlement alluvium" (Daniels and Jordan, 1966; Scully and Arnold, 1981; Grossman, 1983; Knox, 1987; Phillips, 1997; Gomez et al., 2004; Carson, 2006; Lecce, 2007; Rustomji, 2007). If the thickness of postsettlement alluvium, or alluvium deposited by any process, buries a soil by more than 50 cm, these soils are classified as Fluvents because of minimal development. In most cases, if a recent flood deposit is less than 50 cm thick, it is treated as a mapping phase (Soil Survey Staff, 1999, 2010).

33.4.4.4.3 Time

Ripening processes lead to the formation of Fluvents within a few hundred years after drainage from the construction of polders in the Netherlands (Pons and van der Molen, 1973). This is consistent with a compilation of data from quasi-stable floodplains globally (Buol et al., 1997) showing that ochric epipedons commonly form within several hundred years.

Under conditions of landscape stability, Entisols may quickly evolve into other soil orders. In subhumid climates of central Texas and Oregon, for example, Entisols transform into Mollisols and Inceptisols, respectively, within 600 years (Parsons et al., 1970; Nordt and Hallmark, 1990). Further, Entisols transform into Inceptisols and Vertisols within 400 years in slowly aggrading floodplain sediments of the Brazos River in central Texas (Waters and Nordt, 1995). In some humid regions, however, mollic epipedons and Mollisols can develop in as little as 100 years (Ruhe et al., 1975) whereas in other humid regions it takes Entisols 500–600 years to develop into Inceptisols (Bilzi and Ciolkosz, 1977; Scully and Arnold, 1981). Further, Fluvents transform into Inceptisols on levee and point bar facies of the lower Mississippi River valley in less than 600–800 years (Aslan and Autin, 1998). In a subhumid climate of Australia, Walker and Coventry (1976) reported that floodplains that flooded once each year maintained soil development in the Entisol stage, whereas when flood frequencies were on the order of 1–10 years, Mollisols began forming. Fluvents in arid regions can persist for a thousand years in low carbonate parent material and for up to several thousand years in carbonatic parent material (Gile, 1975). Beyond these temporal thresholds, subsurface diagnostic horizons and Aridisols begin to form.

33.4.4.4.4 Parent Material

The distribution of alluvial facies in a floodplain, fan, or deltaic system is dependent on stream type (Chorely et al., 1985), which strongly influences the distribution of pedofacies (see Autin and Aslan, 2001, for example). Sedimentological packages of mixed load, meandering streams in humid regions typically display a fining upward sequence consisting of lower channel, intermediate point bar, and upper floodbasin or levee facies. In some cases, Fluvents form entirely within one of these facies and do not exhibit a noticeable textural change within the solum. If a Fluvent develops in a gradational point bar to floodbasin sequence, for example, a fining upward textural profile will be inherited. In other situations, reverse grading may be encountered. For example, a levee may be deposited over a floodbasin facies, producing a Fluvent with a coarsening upward textural distribution. In addition, suborders of Entisols other than Fluvents may form in floodplains. Psamments sometimes form in sandy channel and point bar deposits and Aquents in poorly drained topographic positions. In contrast to meandering streams, bedload streams or streams near mountain fronts will have a preponderance of Psamments and coastal streams a preponderance of Aquents.

Figure 33.25 is a pedostratigraphic column illustrating some of these fluvial geomorphic principles. The stratigraphic column displays two fining upward point bar to overbank sequences. The first terminates in a buried Fluvent with relict rooting patterns. The Fluvent formed in the upper sedimentological package is a mappable Entisol in the modern floodplain. However, it is buried by postsettlement alluvium. As depicted, the modern buried Fluvent is taxonomically classified, with the postsettlement alluvium characterized as a mapping phase because its thickness is <50 cm (see also Figure 33.24).

33.4.4.4.5 Physical and Chemical Properties

Many alluvial soils are inherently fertile and support some of the most important agricultural centers of the world (Edelman and Van Der Voorde, 1963; Radwanski, 1968; Sidhu et al., 1977). In fact, one-half of Entisols in alluvial settings support up to 1/3 of
FIGURE 33.25 Pedostratigraphic diagram demonstrating fluvial geomorphic principles in relation to a buried and modern Fluvents in a floodplain setting covered by postsettlement alluvium.

the human population for food production (Buol et al., 1997). In the tropics, however, upland soils tend to be depleted in nutrients such that their alluvial counterparts produce low-fertility floodplain soils (Edelman and Van Der Voorde, 1963). This presents even greater food challenges to agricultural production in tropical regions.

As further examples, a floodplain Udifluvent and Torrifluvent display A-C profiles with textural and organic carbon stratification with depth (Table 33.21). There are similarities in clay, silt, and sand content between the two profiles, but the organic carbon content, largely detrital, is greater in the Udifluvent. Consequently, CEC_7 is slightly greater in the Udifluvent than the Torrifluvent. Perhaps the greatest difference in the two profiles is that the Udifluvent is carbonate free with the Torrifluvent having 11%–12% $CaCO_3$ equivalence. This results in a neutral pH and base saturation of ~60%–80% in the udic floodplain soil and a pH of between 8.1 and 8.5 and base saturation of 100% in the torric floodplain soil. The neutral pH of the Udifluvent would lead to greater plant availability of a number of nutrients such as iron and phosphorous (Brady and Weil, 2002). These two examples exemplify the variety of properties possible in Fluvents, largely inherited from the parent material. Soils surrounding the Udifluvent from Missouri

are Alfisols and Inceptisols (Larsen, 2002) with Aridisols and other carbonate-rich soils dominating the drainage basin of the Torrifluvent in southern New Mexico (Gile et al., 1981).

33.4.4.5 Orthents

Orthents are Entisols that do not fit the other suborder categories (e.g., they are the "other Entisols"). They are not water saturated (Aquents), the result of deep mixing or other disturbances by humans (Arents), dominated by sandy textures (Psamments), or stratified recent water-deposited sediments (Fluvents). Instead, most soils that key into this category are on recent erosional surfaces where all former diagnostic horizons have been truncated (Figure 33.26). Other Orthents have formed in recent landslides, mudflows, glacial deposits, piedmont slope deposits, and young terraces, or are in areas of recent solifluction, volcanic deposits, thin regolith over hard rocks, or weakly cemented rock, such as shale (Soil Survey Staff, 1999, 2010).

Orthents occupy approximately 10.5% of the Earth's land surface. They are more extensive than the combined area of the other Entisol suborders, which together occupy an area of about 5.7%. Orthents also have the most taxonomic subdivisions, reflecting lithologic properties inherited from exposed regolith, as well as properties related to climate, depth to bedrock, wetness, shrink-swell, and bioturbation (Soil Survey Staff, 1999, 2010). They occur in any climate and under any vegetation. Orthents in arid and semiarid climates are commonly used for rangeland, wildlife habitat, and irrigated agriculture. In humid regions, Orthents are used for pasture, hay production, cropland, and as forests.

33.4.4.5.1 Other Taxonomic Levels

Orthents are subdivided at the great group level based on the occurrence of udic, ustic, xeric, or aridic moisture regimes, or the cryic temperature regime (Soil Survey Staff, 1999, 2010). At the subgroup level, Orthents are divided according to many features that convey extragrade properties of the soil or to denote transitional intergrades to other taxonomic categories. Extragrades include lithic, lamellic, and vermic properties. Intergrades include durinodic (intergrade to Durids), oxyaquic (intergrade to Aquic subgroups), and aquic (intergrade to Aquents).

33.4.4.5.2 Occurrence and Genesis

Orthents are common in mountainous regions with arid and semiarid climates. An example of these Orthents is illustrated in Figure 33.27 as a block diagram of stepped geomorphic surfaces bordering a major floodplain mapped as Fluvents. Mountains and hills contain Orthents and areas of rock outcrop as the result of rapid erosion and truncation of former diagnostic horizons that were subsequently deposited downslope as colluvium. Widespread erosion of late Pleistocene mountain soils began in the middle Holocene around 7000 years ago in the southwestern United States (Gile et al., 1981). Such sediment makes up the mid-to-late Holocene stepped surface. The elevation of this surface was controlled by the former and slightly higher base level of the river floodplain. A recent lowering of the base level has caused the modern arroyo network to downcut into the Orthents of the Holocene deposits.

FIGURE 33.26 Formation of Orthents by the truncation of diagnostic horizons. Block diagram illustrates an Aridisol with argillic and calcic horizons that are progressively eroded, thus converting the suborders from Argids to Calcids to Orthents. (Modified from Gile, L.H., J.W. Hawley, and R.B. Grossman. 1981. Soil and geomorphology in the basin and range area of southern New Mexico—Guidebook to the desert project. New Mexico Bureau of Mines and Mineral Resources Memoir 39. New Mexico Bureau of Mines and Mineral Resources, Socorro, NM.)

Another location for Orthents in this landscape is the backslope of scarps (risers) associated with the stepped geomorphic surfaces (Figure 33.27). These erosional surfaces are truncating diagnostic horizons of an Aridisol and exhuming underlying sediments beneath the late Pleistocene stepped surface (tread). The rate of erosion on this geomorphic surface is greater than the rate of pedogenesis, and, thus, these soils have no diagnostic horizons other than the ochric epipedon. Sediments generated by erosion on the backslope are deposited on the footslope as unstratified colluvium, which is an example of a geomorphic surface having linked erosional and constructional components. Orthents associated with the erosional component are the same age as Orthents associated with the constructional component because pedogenesis would have started at the same time for both.

Once landscapes have stabilized the type of parent material can affect the rate at which diagnostic horizons form, and,
FIGURE 33.27 Block diagram of stepped geomorphic surfaces bordering a major floodplain illustrating the erosional and depositional occurrence of Orthents. (Modified from Gile, L.H., and R.B. Grossman. 1979. The desert project soil monograph. Doc. PB80-135304. National Technical Information Service, Springfield, VA.)

thus, the length of time a soil remains an Orthent. First, parent materials that contain large amounts of detrital carbonate can curtail the formation of argillic horizons by keeping clay flocculated and less mobile (Gile et al., 1981). Second, parent materials containing plutonic rocks with weatherable minerals and cleavage, such as granites, disintegrate along mineral contacts and produce argillic horizons at a rate faster than parent materials containing volcanic rock, such as rhyolite. This rock type, for example, resists weathering because they lack planes of weakness along which water can enter.

33.4.4.5.3 Physical and Chemical Properties

In contrast to soils classified according to their pedogenically produced diagnostic horizons, the physical and chemical properties of Orthents are mainly inherited from their parent materials. As a result, the range of Orthent properties is wide and reflects the properties of the unconsolidated material in which they occur, combined with bioclimatic factors. Coarse-silty Udorthents in Iowa, for example, have A horizons with organic carbon contents as high as 1.2% and cation exchange capacities of 13.6 cmol$_c$ kg^{-1} (Soil Survey Staff, 1975). In contrast, sandy-skeletal Torriorthents in New Mexico have A horizons with organic carbon contents as low as 0.4% and cation exchange capacities of 7.5 cmol$_c$ kg^{-1} (Gile and Grossman, 1979).

33.4.5 Carbon Stocks

Entisols store approximately 353 Pg (10^{15} g) of total soil carbon (TSC), which is 14.2% of all soil carbon globally (Table 33.22). Of this, 90 Pg (5.8%) of the global soil carbon pool is contained in the organic fraction and 263 Pg (27.7%) in the inorganic fraction. Of the TSC within the Entisol order, 75% is held in the soil inorganic carbon (SIC) pool and 25% in the soil organic carbon (SOC) pool (see also Wilding et al., 2002). This distribution

reflects the presence of calcium carbonate in both pedogenic forms and as detritus in the fine-earth fraction inherited from the parent material (Rabenhorst et al., 1984; Nordt et al., 1998; Kraimer and Monger, 2009). Further, there is more SIC stored in Entisols than any other soil order except Aridisols (Eswaran et al., 2000). In contrast, Entisols store a smaller proportion of the SOC carbon pool globally than most other soil orders.

Orthents store the most TSC (10% globally) of the Entisol suborders (Table 33.22). The SIC pool is high because of the widespread distribution of Orthents in arid lands. After Orthents, Fluvents store more TSC than Psamments and Aquents. The low accumulation of SOC in Aquents is misleading in that their areal extent is limited, even though great groups and subgroups may contain histic and mollic intergrades.

Sequestration rates of atmospheric CO_2 in Entisols are low because of geomorphic processes that limit pedogenesis and the

Eswaran, and H. Scharpenseel (eds.) Global climate change and pedogenic carbonates. Lewis Publishers, Boca Raton, FL.

Arents undetermined.

incorporation of carbon. However, if processes that limit pedogenesis are removed, more organic carbon could be stored in surface horizons during the process of melanization. As with any parent material rich in calcium carbonate, the formation of pedogenic carbonate-carbon would not result in a net accumulation of atmospheric CO_2 (see Nordt et al., 2000). However, Entisols forming in parent materials with weatherable calcium silicate minerals could in the process of forming pedogenic carbonate sequester atmospheric CO_2 at a greater rate than currently.

33.4.6 Conclusions

Entisols are the most widespread soil order in the world forming in a variety of regions reflecting parent material characteristics and geomorphic processes that limit development to A-C or A-R profiles. They typically have ochric epipedons and no subsurface diagnostic horizons. Entisols provide engineering and agricultural challenges in areas that are wet (Aquents or Wassents), sandy (Psamments), flooded (Fluvents), steep or rocky (Orthents), or disturbed by humans (Arents). In contrast, Entisols, especially Torrifluvents, have played an important role in the origins of agricultural centers of early civilizations, such as those along the Nile, Euphrates, Tigris, Indus, and Huang He rivers.

With quasi-landscape stability in parent materials containing weatherable minerals on relatively shallow slopes, Entisols quickly form into one of the other taxonomically defined soil orders accompanied by a variety of physical and chemical changes that includes increased carbon sequestration and storage. Further, Entisols hold more TSC than any other soil order except Aridisols. Fossil Entisols are common in the geologic record as Paleosols and provide information about paleoenvironmental conditions. Entisols capture the essence of challenging pedological problems for the future in response to an ever increasing population and other global change issues related to land use.

33.5 Inceptisols

Wayne H. Hudnall

33.5.1 Introduction

Inceptisols serve two important functions in *Soil Taxonomy*. First, they group soils with incipient soil development (L. *Inceptum*, beginning), and second, they ensure that the classification system is fully bifurcated, that is, all soils fall within some taxa of the classification system. Because of the latter, Smith (1986) referred to Inceptisols as the wastebasket order. They are the repository for all soils that do not meet class differentiae of other orders. While the central concept of Inceptisols is that of soils in cool, very warm humid and subhumid regions that have weekly developed subsoil horizon (cambic) and a light colored surface horizon (Ochric), the order contains a wide variety of soils (Soil Survey Staff, 1998). In some areas, they contain soils with minimal development, while in other areas they represent soils with well-expressed diagnostic horizons that fail the criteria of other orders. All soils that have a plaggen epipedon are Inceptisols (Soil Survey Staff, 1999).

Inceptisols, because of their broad and inclusive nature, served as the precursor for new soil orders (Andisols and Gelisols) and new taxa in other orders. For example, shrink/swell soils with aquic conditions and those with cryic soil temperature regimes previously placed within Inceptisols are now Vertisols (Aquerts and Cryerts). Inceptisols with isomesic or warmer *iso* temperature regimes, previously called Tropepts, are now distributed among other great groups and families of Inceptisols with *iso* temperature regimes. Inceptisols as markers of past cultural habitats and anthropogenic activities (Plaggepts) are now termed Anthrepts, and Ochrepts, a previous suborder of Inceptisols, have now been incorporated into Inceptisols suborders reflecting soil moisture bias. Subaqueous soils formed in freshwater will be classified as Wassepts. Table 33.23 illustrates the dynamics of these changes and how suborders of Inceptisols have evolved with increased knowledge over the past 40 years.

The central concept of Inceptisols includes soils that have undergone modifications of the parent material by structural development and alteration sufficient to differentiate them from Entisols. Pedogenesis may include eluviations (losses of constituents); the translocation of clay, iron, silica, aluminum, carbonates, bases, and organic matter; and the formation of redoximorphic features by aquic (hydromorphic) conditions. Inceptisols occur in all known climates, except under aridic and pergelic conditions, and have many kinds of diagnostic horizons and epipedons. Hence, while the central concept expresses soils with incipient development, Inceptisols are an order with inordinate diversity. No attempt will be made herein to consider their full diversity. Rather, examples of the great range in physical, chemical, biological, and mineralogical attributes of this order pertinent to land use and behavior will be illustrated. For a more extensive coverage of these attributes, the reader is referred to online resources (http://ssldata.nrcs.usda.gov/).

33.5.2 Distribution

The worldwide distribution of Inceptisols is illustrated in Figure 33.28. Because these soils lack a sharply focused central concept, they occur indiscriminately globally. Where Inceptisols reflect youthfulness, they occur in high-gradient mountainous regions, along major river systems as deltaic/fluvial plains, and as soils developed from carbonate-rich bedrocks or sediments in positions of geomorphic instability. Where Inceptisols serve to bifurcate *Soil Taxonomy* there in no particular pattern to their occurrence, but they are commonly dispersed among more strongly developed Alfisols, Ultisols, and Oxisols in tropical and subtropical regions (Figure 33.28).

33.5.3 Formation of Inceptisols

Because soils placed in Inceptisols are varied and represent many different pedogenic processes and combinations of soil-forming factors, examples will be given that typify central concepts or exhibit unique characteristics.

33.5.3.1 Parent Material

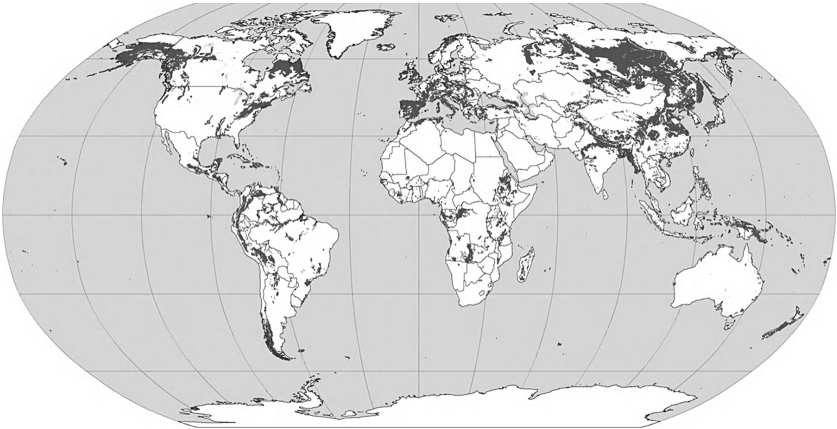
Foss et al. (1983) state that Inceptisols develop on geologically young sediment or landscapes and/or under environmental conditions that inhibit soil development (e.g., coarse-textured siliceous deposits that are resistant to weathering or parent materials within cool climates that inhibit pedogenesis). Given the above constraints, parent materials include almost all types of igneous, metamorphic, and sedimentary materials (residuum, alluvium, colluvium, loess/eolian, glacial drift, etc.). Inceptisols are excluded from soils having a sandy texture throughout because it is believed that pedological features indicative of eluviations, weathering, translocation, and transformation (e.g., development of color Bw horizons) take a very short time to form in subsoils with such low specific surface area coarse-textured materials. The kinds and arrangement of horizons, and their chemical, physical, and mineralogical properties, are controlled to a major degree by the kinds of parent material given from which Inceptisols have developed. For example, fine-textured parent materials give rise to clayey Inceptisols, acidic parent materials result in base-poor (Dystr)


FIGURE 33.28   Global distribution of Inceptisols. (Courtesy of USDA-NRCS, Soil Survey Division, World Soil Resources, Washington, DC, 2010.)

Inceptisols, and calcareous parent materials form neutral or alkaline, base-rich (Eutr) Inceptisols. Depth, color, organic carbon content, and drainage frequently reflect the combination of geomorphic position, landscape instability, and nature of the parent materials.

Table 33.24 illustrates the diversity in selected physical, chemical, and mineralogical properties of soils developed from six different parent materials [e.g., Mississippi River alluvium (*Fluvaquentic Epiaquepts*); noncalcareous glacial outwash (*Aeric Fragiaquepts*); Permian red bed shales (*Vertic Calciustepts*); basic igneous rock (Oxic Haplustepts); colluviums weathered from sandstone, siltstone, and shale (Typic Dystrudepts); and Coastal Plains alluvium (Typic Sulfaquepts)]. Abridged attributes of

these soils follow with detailed morphological, physical, chemical, and mineralogical data found online at Soil Survey Data Mart.

33.5.3.1.1 Fluvaquentic Epiaquepts (Conciene Series)

These soils developed from loamy alluvial sediments that have weathered into soils with moderately expressed cambic horizons. Their nearly level to depressional landforms favors restricted drainage, especially under humid climates. Under slightly better drained conditions, soils developed in this alluvium may form argillic horizons in a relatively short time (hundreds to several thousand years). This is because the eluviation–illuviation process proceeds relatively rapidly in such permeable, base-rich, medium textured parent sediments.

33.5.3.1.2 *Vertic Calciustepts (Vernon Series)*

The calcareous clays and shales of the Permian red beds restrict water percolation and profile development. Well-drained soils that develop in these sedimentary materials have a calcic or salic horizon whereby lithogenic carbonates and soluble salts have been translocated to subsoils and precipitated as pedogenic products at the terminus of the wetting front. The depth of carbonate and salt translocation, degree of calcic or salic horizon expression, and thickness of the cambic horizons are conditioned by the landform position, texture, and permeability of the parent materials.

33.5.3.1.3 *Oxic Haplustepts (Kahana Series)*

These well-drained, clayey soils have developed in basic igneous rocks in Hawaii. Under a warm, tropical environment, the weathering of nonresistant mafic-rich minerals and fine grained to amorphous materials has been rapid. An oxic-like (sesquioxide rich, subactive clay) cambic subsoil has developed. On a stable landform position, under an ustic moisture regime, subsequent weathering over time will result in an Oxisol with low activity clay.

33.5.3.1.4 *Aeric Fragiaquepts (Volusia Series)*

These soils have developed from weakly or noncalcareous glacial outwash of stratified sand, silt, and gravel. Upon weathering, these poorly sorted materials form loamy pans that have a brittle or fragic rupture upon deformation (fragipans). Weathering discontinuities in these materials enhanced by textural stratification are believed to result in a weak cementation between closely packed skeleton grains (Smeck et al., 1989). The bonding agents between the grains are believed to be hydrous oxides of Al and Si and/or translocated clay coatings or bridges. Restricted drainage would complement transport discontinuities in these soils to form weathering discontinuities.

33.5.3.1.5 *Typic Dystrudepts (Fedscreek Series)*

These well-drained soils form under udic moisture regimes in loamy colluviums weathered from sandstone, siltstone, and shale. The parent materials consist of acid channery-sized skeletal materials. Because the chemical and physical buffering capacity of the colluvium is low, and the parent materials are siliceous clasts, very acid conditions develop upon weathering. Profile development within solum, however, is minimal because the preweathered clasts are resistant to further decomposition and disintegration. Hence, release of clay and other products of weathering for subsequent translocation and transformation are limited. Again, the nature of the parent material has been pivotal in governing the intensity, modes, and mechanisms of pedogenesis in these coarse-textured, highly permeable, acid upland soils.

33.5.3.1.6 *Typic Sulfaquepts (Gimhae Series)*

These soils are common along coastlines with tidal influence. Here, the parent materials are medium textured alluvial deposits, usually associated with deltas or depositional regions of rivers that empty into the ocean. These wet environments are favorable for the accumulation of metal sulfides (e.g., pyrite), which upon drainage (natural or artificial) oxidize to form sulfuric acid and other acid sulfate weathering products (Van Breeman, 1982). Sulfaquepts are important soils because of their land use, distribution, and behavior are conditioned by their acidic character.

33.5.3.2 Climate

Inceptisols occur in subhumid to humid climates from equatorial to tundra regions where, if they have permafrost within 2 m, they are replaced by Gelisiols (Soil Survey Staff, 1998, 2010). Inceptisols cannot have an aridic (torric) moisture regime unless they have an Anthropic epipedon, which causes them to become Anthrepts.

Soil temperature and moisture are used at the suborder level in *Soil Taxonomy* to reflect major controls on current soil-forming processes. Such controls influence not only rates, modes, and mechanisms of physical and chemical weathering, but also biological and geomorphic processes that influence relief, landscape stability, topography, and soil drainage. Because Inceptisols form over a wide range of climatic conditions, excluding aridic and pergelic, the climatic impact on Inceptisols is similar to that of most other orders.

Soil moisture regime is used as a differentiation for four Inceptisols suborders (Aquepts, Udepts, Ustepts, and Xerepts), soil temperature regime for one suborder (Cryepts), and past human cultural impacts for one suborder (Anthrepts). For Cryepts, it was judged that temperature constraints on pedogenesis, use and management were more important than moisture constraints, even though both are important; the soil temperature regime was used as a differentiation at the family level for all orders except Gelisols and those soils that have a cryic soil temperature regime. Anthrepts have no particular climatic bias and are of limited geographical extent.

Aquepts form under aquic or excess wetness conditions (saturation with water, periodic reduction, and formation of contemporaneous redoximorphic features, redox concentrations and/or depletions). Udepts form under better drained, strongly leaching environments, where precipitation exceeds evapotranspiration. These soils generally lack salts and carbonates in the solum and have undergone moderate to strong weathering. Generally, summer periods of soil moisture deficit are insufficient to negatively impact mesophytic agricultural crops. Ustepts are formed under drier climates with significant periods of summer soil moisture deficit. Precipitation is less than evapotranspiration, at least during significant periods of the summer. They commonly exhibit incomplete leaching, weak to moderate weathering intensities, and pedogenic salts and/or carbonates in the lower solum. Moisture deficit is sufficiently severe to limit crop growth during summer months. Xerepts are similar to Ustepts but are formed in climates where winter precipitation is dominant. These soils are common in Mediterranean regions of Europe and along the Pacific coastal zones of western United States. The Cryepts serve as an interface between the cold soils of high latitudes

with pergelic conditions (permafrost within 2 m) and cold soils of temperate region or orographic mountainous zones without permafrost within 2 m.

In Table 33.24, the climate effects on soil classification and corresponding properties are illustrated for a few pedons. Vertic Calciustepts (*Vernon series*) and Oxic Haplustepts (*Kahana series*) are examples of soils with an ustic moisture regime and contrasting cambic horizon composition, development, and chemical characteristics. The Calciustepts are incompletely leached, have carbonates throughout the pedon, and have a clay mineral composition that favors shrink/swell activity with changing moisture content. Comparison between Fluventic Haploxerepts (*Vidhas series*) and Humic Dystrocryepts (*Moran series*) reflecting contrasting temperature and precipitation regimes due to elevation differences. Although parent materials are different, climate is the major determinant governing increased organic matter contents in the Humic Dystrocryepts, which formed under udic moisture and cryic temperature regimes about 1050 m elevation. This is compared to the Fluventic Haploxerepts formed under xeric moisture and thermic temperature regimes at an elevation of about 90 m. The Dystrocryepts have accumulated much greater organic carbon contents in the Histic layer (Oi) overlaying and umbric epipedon and a low base subsoil. In contrast, the Haploxerepts have accumulates much less organic matter in the ochric epipedon, and the presence of carbonates distributed throughout the profile implies weak leaching potentials. Climate, in this example, is considered an intensity factor whereby the rate of soil development increases as temperature and rainfall increase, but decreases as either decreases. Limit soil moisture during periods of optimal soil weathering limits profile development in the Haploxerepts. In contrast, the Dystrocryepts have optimal moisture for pedogenesis, but the soil temperature is limiting.

33.5.3.3 Topography

The topography associated with many Inceptisols is a sloping to strongly sloping landscape subject to erosion rates that are equal to or greater than soil formation rates. Many Inceptisols occur on hillsides of major mountains throughout the world. Profile developments here are constrained by unstable landforms and cool climates. Youthful Inceptisols are common also on nearly level fluvial, lacustrine, and deltaic plains (or associated depressions) where profile development is limited by age of the sediments and/or shallow groundwater tables. Coastal estuaries are also probable locations for Inceptisols, especially those where metallic sulfides and sulfates are likely to accumulate. Subaqueous condition favor the formation of the cambic horizon of the soils formed before subsidence and sea level rise. Processes that are active for subaqueous conditions that form cambic horizons have not been extensively studied.

33.5.3.4 Vegetation

It is difficult to isolate vegetation as an independent soil-forming factor governing the synthesis of Inceptisols because vegetation is dependent on climate and topography. Interdependency of these factors is easily demonstrated by comparing the Humic Dystrocryepts (*Moran series*) and Vertic Calciustepts (*Vernon series*) of Table 33.24. Dystrocryepts support mountain meadow and alpine vegetative communities such as Kobres (*Koberesia* sp.), Asters (*Aster* sp.), and Yarrow (*Achillea* sp.) under cold, moist climates. Under hotter, drier conditions of the Calciustepts, native vegetation is mixed, midgrass prairie consisting of buffalograss (*Buchloe dactyloides*), Grama grasses [blue (*Bouteloua gracilis*), hairy (*B. hirsuta*), and sideoats (*B. curtipendula*)], and tobosa grass (*Hilaria mutica*). Primary productivity, accumulation of soil organic matter, and leaching potentials are governed by effective soil moisture and temperature regimes. Effects on soil properties are remarkably evident in these two soils (Table 33.24). Primary productivity for the Dystrocryepts is limited by soil temperature regime while a seasonal soil moisture deficit limits primary productivity for Calciustepts. Higher organic matter accumulation, low turnover rates, and moderate to strong leaching potentials (acid subsoils) are consequences in Dystrocryepts. In contrast, lower organic matter contents, high turnover rates, and less effective leaching potentials (calcareous solum) occur in Calciustepts.

33.5.3.5 Time

Many examples are available in the literature to demonstrate that time is a soil-forming factor (Jenny, 1941, 1980). Some might argue that factors other than time have more influence on soil formation. While this may be true in some cases, time in combination with the intensity factor (climate) has been responsible for many attributes of Inceptisols. Inceptisols are usually considered immature soils, but some have advanced stages of development and are just short of completing their evolutionary cycle from Entisols to Oxisols. For example, Oxic Haplustepts are similar to Oxisols but either have oxic conditions too deep in the soil (greater than 150 cm) or have CEC charge characteristics just a little too high for oxic horizon requirements—a prerequisite for all Oxisols. Upon erosion and truncation, some Inceptisols have soil properties at depths associated with old stable landforms prior to dissection. Further, several taxonomic classes of Inceptisols have morphological features that could be interpreted either as youthful or an advanced stage of pedogenesis. Arenic Eutrudepts is one such example in which the soils may have developed from recent sandy sediments or may be residuum from weakly consolidated sandstone on old stable landforms.

33.5.4 Morphology

Inceptisols have many kinds of diagnostic horizons and epipedons, but the most common sequence of horizons is an ochric or umbric epipedon overlying a cambic or fragipan horizon. However, a cambic horizon is not required if an umbric, histic, or plaggen epipedon is present or if there is a fragipan, duripan, placic, calcic, petrocalcic, gypsic, petrogypsic, salic, or sulfuric horizon (Soil Survey Staff, 1998, 2010). They can also have anthropic and mollic epipedons but not argillic, kandic, or natric horizons unless buried below recent sediments. Oxic horizons are permitted only if the upper boundary is deeper than

150 cm. Spodic horizons are permitted only if they are less than 10 cm thick or if the upper boundary is deeper than 50 cm.

It is clear from the above discussion that the number and kinds of processes active in Inceptisols and the definition of Inceptisols are unavoidably complex because the order serves dual functions in grouping soils of minimal pedogenic development and bifurcating *Soil Taxonomy*. In summary, they are youthful soils in rejuvenated landscapes but pedogenetically advanced on more stable landforms. Their attributes are highly variable and seldom uniquely definitive.

33.5.5 Pedogenic Processes

Pedogenic processes common to Inceptisols have been briefly considered under Section 33.5.3. Such processes are converged in greater detail in Chapters 30 and 31. The processes germane to Inceptisols are combinations and complexes of subprocesses and reactions found in most other soil orders. The nature of these processes, including their terminology, is reviewed by Marbut (1921), Kellogg (1936), Byers et al. (1938), Simonson (1959), Buol et al. (1980), Arnold (1983), Fitzpatrick (1986), and Fanning and Fanning (1989).

Biological processes including establishment of macro and micro fauna and flora, microbial and fungal mineralization, decomposition (mummification) and accumulation of organic matter, biotic transformations (e.g., ammonification, nitrification, denitrification, and nitrogen fixation), and pedoturbation are important in epipedon and cambic horizon genesis. Chemical processes including hydration, hydrolysis, solution, mineral synthesis, and oxidation/reduction reactions are responsible for both epipedon and cambic horizon synthesis. Physical processes contribute to the formation of pedogenic structure (obliteration of at least 50% of the "rock" structure) and transport of materials within the solum. They include aggregation, expansion/contraction (shrink/swell), freeze–thaw, and mass transport by solution or suspension (translocation).

Formation of a cambic horizon requires conversion of rock structure to soil structure (peds) and evidence of at least one of the following: oxidation/reduction (aquic conditions); neoformations of clay; translocation of salts, carbonates, clay, and/or organic–metal complexes; or liberation of free iron oxides. The cambic horizon is a prerequisite for most Inceptisols, but exceptions occur for certain epipedons or subsurface diagnostic features (Section 33.5.3).

Illuviation and/or neosynthesis of clay and organic–metal complexes cannot be of such magnitude that argillic, natric, kandic, or spodic horizons are formed, unless buried. Processes responsible for formation of oxic horizons include desilication, neoformation of low activity clays, and/or residual concentration of secondary oxides and oxyhydroxides of iron and aluminum (Kellogg, 1936; Sivarajasingham et al., 1962; Cline, 1975; Jenny, 1980). Acid sulfate soils are formed by processes termed sulfidization and sulfurization. These processes are responsible for the accumulation of metal sulfides in soils and sediments, oxidation of these sulfides, formation of sulfuric acid, ferrolysis, soil acidification, and mineral dissolution (Kittrick et al., 1982; Van Breeman, 1982; Fanning and Fanning, 1989).

33.5.6 Classification

In the 1938 classification scheme (Baldwin et al., 1938) and in most subsequent revisions in the United States prior to *Soil Taxonomy*, Inceptisols were included in a number of great soil groups including Ando, Hydro Humi Latosols, Humic Gley, Tundra, Half Bog, Sols Bruns Acids, Brown forest, Regosols, Lithosols, Aluvial, and numerous other minor groups (Foss et al., 1983). Even at that time, this was a very extensive and diverse taxa of soils. In the Canadian soil classification system, the wet Inceptisols (Aquepts) were classified as Gleysols but most of the better drained members were Brunisols. In the legend of the FAO/UNESCO soil map of the world (FAO-UNESCO, 2003), most well-drained Inceptisols would be classed as Cambisols or Phaeozems if the base saturation is low. The wet Inceptisols would be classed mostly as Gleysols except those with acid sulfate conditions, which would be grouped with Fluvisols.

Inceptisols suborders, great groups, and subgroups are represented in Table 33.25. Rationale for these taxa has been considered previously in this chapter and in Chapter 32. The following discussion of suborders has been taken directly from *Soil Taxonomy* (1998) to illustrate the general nature and characteristics of Inceptisols suborders.

33.5.6.1 Anthrepts

These are the Inceptisols that are the more less freely drained that have either an anthropic or a plaggen epipedon. Most of these soils have been used as cropland or places of human occupation for many years. They can have almost any temperature regime, and almost any vegetation. Most of them have a cambic horizon. Only two subgroups are recognized at this time, those with plaggen epipedons indicative of ancient cultural sites (*Plaggenanthrepts*), and those with anthropic epipedons reflecting other long-term human impacts on soils such as irrigated farmlands or housing areas. Most of these soils are in Eurasia or Northern Africa.

33.5.6.2 Aquepts

These are the wet Inceptisols. Their natural drainage is poor or very poor and, if they have not been artificially drained, groundwater is at or near the soil surface at some time during normal years but typically not during at all seasons. They mostly have a gray to black surface horizon and gray subsurface horizon with redox concentrations that begin at a depth of less than 50 cm. A few have a brownish surface horizon that is less than 50 cm thick.

Most Aquepts have developed in late Pleistocene or younger deposits in depressions, nearly level plains, or floodplains. They occur from the equator to latitudes with discontinuous permafrost. The common features of most of these soils are the gray and rusty colors of redoximorphic features at a depth of 50 cm or less and the shallow groundwater or artificial drainage. They may have almost any particle size class except fragmental, and any reaction class, any temperature regime except pergelic, and almost any

TABLE 33.25 Listing of Suborders, Great Groups, and Subgroups for Inceptisols Order

Suborder	Great Groups	Subgroups
Aquepts	Sulfaquepts	Salidic, Hydraquentic, Typic
	Petraquepts	Histic Placic, Placic, Plinthic, Typic
	Halaquepts	Vertic, Aquandic, Duric, Aeric, Typic
	Fragiaquepts	Aeric, Humic, Typic
	Cryaquepts	Sulfic, Histic Lithic, Lithic, Vertic, Histic, Aquandic, Fluvaquentic, Aeric Humic, Aeric, Humic, Typic
	Vermaquepts	Sodic, Typic
	Humaquepts	Hydraquentic, Histic, Aquandic, Cumulic, Fluvaquentic, Aeric, Typic
	Epiaquepts	Vertic, Aquandic, Fluvaquentic, Fragic, Aeric, Humic, Mollic, Typic
	Endoaquepts	Sulfic, Lithic, Vertic, Aquandic, Fluvaquentic, Fragic, Aeric, Humic, Mollic, Typic
Anthrepts	Plagganthrepts	Typic
	Haplanthrepts	Typic
Cryepts	Eutocryepts	Humic Lithic, Lithic, Andic, Vitrandic, Aquic, Oxyaquic, Lamellic, Xeric, Ustic, Humic, Typic
	Dystrocryepts	Humic Lithic, Lithic, Andic, Vitrandic, Aquic, Oxyaquic, Lamellic, Spodic, Xeric, Ustic, Humic, Typic
Gelepts	Humigelepts	Lithic, Andic, Aquic, Oxyaquic, Fluventic, Turbic, Eutric, Typic
	Dystrogelepts	Lithic, Andic, Aquic, Fluventic, Turbic, Eutric, Typic
	Haplogelepts	Lithic, Andic, Aquic, Fluventic, Turbic, Eutric, Typic
Ustepts	Durustepts	Typic
	Calciustepts	Lithic Petrocalcic, Lithic, Torrertic, Vertic, Petrocalcic, Gypsic, Aquic, Aridic, Udic, Typic
	Dystrustepts	Lithic, Andic, Vitrandic, Aquic, Fluventic, Oxic, Humic, Typic
	Haplustepts	Aridic Lithic, Lithic, Udertic, Torrertic, Vertic, Andic, Vitrandic, Anthraquic, Aquic, Oxyaquic, Oxic, Lamellic, Torrifluventic, Udifluventic, Fluventic, Gypsic, Haplocalcidic, Calcic, Udic, Calcic, Aridic, Dystric, Udic, Typic
Xerepts	Durixerepts	Aquandic, Andic, Vitrandic, Aquic, Entic, Typic
	Calcixerepts	Lithic, Vertic, Petrocalcic, Sodic, Vitrandic, Aquic, Typic
	Fragixerepts	Andic, Vitrandic, Aquic, Humic, Typic
	Dystroxerepts	Humic Lithic, Lithic, Aquandic, Andic, Vitrandic, Anthraquic, Fragiaquic, Fluvaquentic, Aquic, Oxyaquic, Fragic, Fluventic Humic, Fluventic, Humic, Typic
	Haploxerepts	Humic Lithic, Lithic, Vertic, Aquandic, Andic, Vitrandic, Gypsic, Aquic, Lamellic, Fragic, Fluventic, Calcic, Typic
Udepts	Sulfudepts	Typic
	Durudepts	Aquandic, Andic, Vitrandic, Aquic, Typic
	Fragiudepts	Andic, Vitrandic, Aquic, Humic, Typic
	Calciustepts	Lithic Petrocalcic, Lithic, Torrertic, Vertic, Petrocalcic, Gypsic, Aquic, Aridic, Udic, Typic
	Dystrudepts	Lithic, Andic, Vitrandic, Aquic, Fluventic, Oxic, Humic, Typic

vegetation. Most of them have a cambic horizon, and some have a fragipan. It is possible that some have a plaggen epipedon.

Table 33.25 lists the nine great groups of Aquepts. These great groups are based upon limiting features or horizons that impact use, management, and behavior. Specifically, these include soils with acid sulfuric horizons within 50 cm of the surface associated with oxidation of metal sulfides (*Sulfaquepts*); soils with a restrictive cemented subsurface horizon that forms a continuous phase within 100 cm of the soil surface (*Petraquepts*); salty (salic) or alkali (natric) subsoil horizons (*Halaquepts*); soils with fragipan (*Fragiaquepts*); soils with a cryic temperature regime (*Cryaquepts*); soils with strongly bioturbated layers by macrofauna such as crayfish, worms, and mammals (*Vermaquepts*); soils with darkened, organic-enriched surface horizons (*Humaquepts*); soils with a perched water table (*Epiaquepts*); soils that are saturated from a groundwater source (*Endoaquepts*).

33.5.6.3 Cryepts

Cryepts are the cold Inceptisols of high mountains or high latitudes. They cannot have permafrost. The vegetation is mostly conifers or mixed conifers and hardwood trees. Few of them are cultivated. These soils may be formed in loess, drift, alluvium, or solifluction deposits, mostly late Pleistocene or Holocene in age. They commonly have a thin, dark brownish ochric epipedon and a brownish cambic horizon. Some have bedrock within 100 cm of the surface. In the United States, these soils are moderately extensive in the high mountains of the West as well as other mountainous areas of southern Alaska and the world.

Two great groups of Cryepts are recognized (Table 33.25). Those that are calcareous or have high base saturation are *Eutocryepts*, and Cryepts with low base saturation are *Dystrocryepts*.

33.5.6.4 Udepts

Udepts are mainly the more or less freely drained Inceptisols that have a udic or perudic moisture regime. They formed on nearly level to steep surfaces mostly of late Pleistocene or Holocene age. Some, where the soil moisture regime is perudic, formed in older deposits. Most them had or now have a forest vegetation, but some have shrub or grass. A few have been formed from

Mollisols by truncation of the mollic epipedon (*Eutrudepts*), mostly under cultivation. Most of them have an ochric or umbric epipedon and a cambic horizon with low base saturation (*Dystrudepts*). These were the Sols Bruns Acides of earlier classification schemes (*Fragiudepts*), or a duripan (*Durudepts*). In the United States, Udepts are most extensive on the Appalachian Mountains, the Allegheny Plateau, and the West Coast; they also occur extensively in Eurasia.

33.5.6.5 Ustepts

Ustepts are the more or less freely drained Inceptisols that have a ustic moisture regime. They have dominantly summer precipitation or an isomesic, hyperthermic, or warmer temperature regime. Many of these soils are calcareous at a shallow depth and have a Bk or calcic horizon (*Calciustepts*). A few have formed from Mollisols by truncation of the mollic epipedon, mostly under cultivation. Most of them have an ochric or umbric epipedon and a cambic horizon (*Haplustepts*). Some have a duripan (*Durustepts*), especially in areas where a labile silica source is associated with pyroclastic deposits or volcanic ash. Ustepts with low base saturation (*Dystrustepts*) occur in areas with polycycled preweathered acidic sediments or outcrops of acid bedrocks common in West Africa and isolated areas of the United States. The native vegetation commonly was grass, but some supported tress and savannas. Ustepts are of moderate extent in the United States. They are most common on the Great Plains mostly in Montana, Texas, and Oklahoma. They occur extensively in ustic sectors of the Americas, Eurasia, West Africa, and several island countries.

33.5.6.6 Xerepts

Xerepts are the more or less freely drained Inceptisols that have a xeric moisture regime, dominantly winter precipitation. They have a frigid, mesic, or thermic temperature regime. They formed mostly in Pleistocene or Holocene deposits or on steep slopes. Many of these soils are calcareous at a shallow depth and have a Bk, a calcic, or a petrocalcic horizon (*Calcixerepts*). Others have low base saturation (*Dystrixerepts*). Most of them have an ochric or umbric epipedon and a cambic horizon (*Haploxerepts*). Some have a duripan (*Durxerepts*) and a few have a fragipan (*Fragixerepts*). The native vegetation was commonly coniferous forest on those with a thermic temperature regime. These soils are of moderate extent in the United States. They are most common near the West Coast in the States of California, Oregon, Washington, Idaho, and Utah. They are the major soils of the Mediterranean regions of Eurasia and Northern Africa.

33.5.7 Physical, Chemical, and Mineralogical Properties

Because of the diverse nature of Inceptisols, few generalized statements can be made about their physical, chemical, biological, and mineralogical properties. Their properties are nearly as inclusive as all the other soil orders collectively. Inceptisols span the global regions from intensively weathered to minimally developed soils. For example, they are acidic to alkaline in reaction, weak to strongly physic-chemically buffered, have low to high organic matter contents, low to high hydraulic transport functions, low to high water retention values, fertile to infertile in nutrient status, etc. The *Soil Survey Manual* (Soil Survey Staff, 1993) identifies class ranges for the above classes and for many other soil attributes described and measured. Table 33.24 illustrates the kind of magnitude of diversity vested in many of these Inceptisols attributes. The database online for Inceptisols (http://soildatamart.nrcs.usda.gov/) further documents this aspect.

The reader is referred to discussions of other orders in Sections 33.2 through 33.13 for physical, chemical, biological, and mineralogical attributes likely to be associated with Inceptisols. For example, those Inceptisols with andic surface materials are similar to Andisols; those with vertic shrink/swell features to Vertisols; those with calcic, gypsic, salic, petrocalcic, and petrogypsic horizons to Aridisols; those with translocation and/or neosynthesis of clay or organic–metal colloids to Alfisols, Ultisols, and Spodosols; those with high sesquioxide contents and/or low activity clay mineral suites to Oxisols; and those with cryic temperature regimes to Gelisols.

The sand and silt mineralogy commonly consists of quartz, mica, and feldspars with minor components of weatherable heavy minerals (opaque). The opaque minerals in soils derived from basic bedrocks are feldspars, hematite, magnetite, ilmenite, and rutile. Inceptisols rich in sesquioxides (Oxic subgroups) comprise oxyhydroxides of Fe, Al, and Ti including gibbsite, hematite, goethite, boehmite, rutile, and anatine. Those soils associated with drier climates (Ustepts and Xerepts) contain soluble salts (e.g., $NaCO_3$, $NaSO_4$, and $NaCl$), gypsum and carbonates (calcite and dolomite). Inceptisols with andic and vitrandic materials (pyroclastics) contain amorphous or short-range order minerals such as allophone, ferrihydrite, and glasses. Phyllosilicate clay minerals range from smectite, mica, kaolinite, chlorite, vermiculate, and mixed layer assemblages to rather unique suites dominated by serpentine and glauconite. In acid sulfate soils (e.g., Sulfaquepts and Sulfudepts), jarosite is a common constituent that marks very acid conditions associated with metal sulfide oxidation. Pedogenic gypsum is also common in these soils.

33.5.8 Management

For management purposes, Inceptisols can be subdivided into three land uses, namely forestry, pasture production, and agronomic cropping.

33.5.8.1 Forestry

Most Inceptisols under forested land use occur in mountainous regions on slopes ranging from 3% to 90%. On steep terrains, management systems other than natural regrowth are environmentally unacceptable and practically impossible. Most forested Inceptisols have carbon contents sufficiently high as long as the surface is not eroded, that indigenous nutrient recycling is sufficient to sustain growth without external fertilizer amendments. On less sloping terrain, many large, commercial timber

companies find fertilizer amendments, especially phosphorous applications, to be economically beneficial. Management techniques to control competition from unwanted species and disease suppression commonly involve controlled burns or physical removal of dead or unwanted species. Harvesting methods depend on the slope gradient; they range from surface skidding to aerial removal by helicopter or cable lifts. Harvest schemes may involve clear cutting or selective harvesting. Damages from erosion and compaction of harvest operations on less sloping Inceptisols are commonly ameliorated with surface tillage operations on less sloping Inceptisols are commonly ameliorated with surface tillage operations to break up surface crusts, compacted zones and to establish soil and water conservation buffers.

33.5.8.2 Pasture Production

Most of the Inceptisols under pasture management are planted to improved pastures that respond to N, P, and K fertilization, especially if the pasture is intensely managed for animal or forage production. Areas, which occur under native range, or under shifting traditional agriculture as in developing countries, should be managed using best management practices for stocking rate, pasture rotation, and fallow period. These vary from one region to another, not only in terms of soil conditions but also in terms of the ability of the operator to provide investment inputs. Commonly under traditional agriculture, the inputs are minimum and the soil dictates the best management and utilization practices to be followed. Inceptisols with an ustic or xeric moisture regime are limited by insufficient rainfall. Irrigation may be used to supplement natural precipitation on some Inceptisols, but the cost of this investment for improved pastures may make it economically unattractive. However, many examples of irrigated improved pastures occur in Europe and the United States where the economics are favorable and adequate high quality aquifers are available. Surface or subsurface drainage may be required to remove surface water or lower the water table for optimal forage production, especially for Aquepts.

33.5.8.3 Agronomic Cropping

Inceptisols are the major soils on which agronomic crops are produced in some parts of the world. Aquepts, Cryepts, Udepts, Ustepts, and Xerepts are very productive and valuable agricultural land resources, if properly managed. Crops produced depend on climate (length of growing season, dependability of precipitation, seasonal periods of soil moisture excess or deficit, photoperiodism, degree days, etc.), but because of Inceptisols diversity, most major food, feed, and fiber crops are included. Irrigation is used on vegetable, citrus, and other important cash or specialty crops when summer periods of moisture deficit become extreme. The highly weathered Inceptisols within the tropics are used for sugarcane, pineapple, cotton, and some upland rice production with many of these crops being produced under irrigation. Most of these soils respond to N, P, and K fertilizers and some soils require lime in order to neutralize acidity and sustain production.

Cryepts are used mostly for cereal crops because of the short growing season, photoperiodism, and few number of degree days. Sometimes these soils are used for cool season vegetables and forage production. Where these soils interface with Gelisols, they are constrained by cold soil temperatures, freeze–thaw heaving, and erosion induced by wind, water, and mass movement (solifluction). They may be under alpine meadow.

Aquepts used for agronomic production usually require surface or internal drainage but depending on soil temperature, a wide range of crops are grown including cotton, sugarcane, rice, and corn in the subtropical and tropical climates and corn, soybeans, sorghum, and some cereal crops in temperate climates. Sulfaquepts (and Sulfudepts) require specialized management because when they are drained mainly for lowland rice production, the sulfuric horizon produces large amounts of sulfuric acid. Because the reactions involved were not well understood when most of these soils were drained, vast wastelands were created. Management schemes, which reduce acid production, have been developed by Ponnamperuma et al. (1973), Cisse et al. (1993), Van Breeman (1982), and Coly (1996). Reclamation and management practices for acid sulfate soils have been proposed by Van Breeman (1982), Rimwanich and Suebsuri (1983), and Coly (1996). The formation of a sulfuric horizon should be prevented or minimized by controlling the depth of the water table upon drainage (keeping the soils saturated to prevent pyrite oxidation). Sulfaquepts can be reclaimed by inducing reducing conditions within the sulfuric horizon and/or flushing the soil to remove the sulfuric acid. The flushing can be accomplished using a combination of saline and freshwater to remove the soluble salts. The addition of $CaCO_3$ is required to neutralize any acidity produced, and $CaSO_4$ is required when saline water has been used for reclamation to remove excess sodium (Cisse et al., 1933; Coly, 1996).

33.6 Gelisols

J.G. Bockheim

C. Tarnocai

33.6.1 Introduction

Gelisols, which are the permafrost-affected soils, constitute the 12th and newest soil order. They comprise 18 million km^2 or about 13% of the Earth's land surface and occur in the Arctic, Subarctic, Boreal, Antarctic, Subantarctic, and some alpine regions under cold continental, subhumid or semiarid, and arid conditions (Bockheim et al., 1994). They are either unvegetated or support continuously vegetated tundra, subarctic and boreal forest, and some alpine tundra. Gelisols are of global concern because they contain many protected areas, support numerous indigenous populations who depend on the land and surrounding oceans for sustenance, and may be subject to considerable impacts from human development (oil, coal and gas exploration, and mining) and global warming.

Gelisols are defined as soils having permafrost within 100 cm of the soil surface, or gelic materials within 100 cm of the soil surface and permafrost within 200 cm of the soil surface (Soil Survey Staff, 2010). Gelic materials, in turn, are seasonally or perennially frozen mineral or organic soil materials that have evidence of cryoturbation (frost churning), ice segregation, or cracking from cryodesiccation. Gelic materials contrast with other kinds of materials, such as andic or spodic materials, in being defined entirely on the basis of physical and thermal characteristics, rather than chemical properties.

A representative Gelisol is shown in Figure 33.29. Gelic materials occur in both the active layer and the upper part of the permafrost as evidenced by cryoturbation, denoted in soil descriptions by the subscript jj (y in the Canadian system).

33.6.2 Permafrost and the Occurrence of Gelisols

Gelisols only occur in areas containing permafrost within 100 cm of the soil surface if the soil is not cryoturbated or 200 cm of the surface if the soil is cryoturbated. Permafrost is defined
FIGURE 33.29 An aquaturbel developed on an earth hummock in northern Canada. The Canadian soil horizon nomenclature is used, where L–H = Oi–Oa, y = jj, and z = j in *Soil Taxonomy*.

here as a thermal condition in which a material (including soil materials) remains below 0°C for 2 or more years in succession. Permafrost may be ice-cemented (designated in soil descriptions with the subscript fm) or in the case of insufficient interstitial water, dry (designated as f). In the frozen layer, a variety of ice lenses, vein ice, segregated ice crystals, and ice wedges may be evident. An important consideration is that the permafrost is in dynamic equilibrium with the environment.

Permafrost, which comprises about 13% of the Earth's surface and 24% of the northern hemisphere, is differentiated into four zones on land in the circumpolar regions: continuous (91%–100% cover), discontinuous (51%–90% cover), sporadic (10%–50% cover), and isolated (<10% cover) patches (Figure 33.30).

The distribution and thickness of permafrost are influenced by natural surface features, such as snow and vegetation cover, topography, and bodies of water, but as Figure 33.30 shows, are most affected by regional climate.

33.6.3 Description and Distribution of Gelisols

There are three suborders within the Gelisol order (Soil Survey Staff, 2010): Histels, Turbels, and Orthels that are differentiated on the basis of organic matter content and for mineral soils whether or not there is cryoturbation. Distribution of Gelisols is depicted in Figure 33.31. Suborders, great groups, and subgroups are shown in Table 33.26.
FIGURE 33.30 Distribution of permafrost in the northern hemisphere. (From Brown, J., O.J. Ferrians, Jr., J.A. Heginbottom, and E.S. Melnikov. 1997. FIGURE 33.31 Distribution of Gelisols by dominant suborder in the circumarctic region. (From Tarnocai, C., D. Swanson, J. Kimble, and G. Broll. 2007. Northern circumpolar carbon database. Digital Database, Research Branch, Agriculture and Agri-Food Canada, Ottawa, Canada. With permission.)

33.6.3.1 Histels

Histels are Gelisols that have 80% or more (by volume) of organic materials from the soil surface to a depth of 50 cm, or to a restricting layer (Figure 33.32a). Histels otherwise meet the requirements of a Histosol except for the presence of permafrost within the upper 100 cm. Histels comprise 15% of the Gelisols in the circumarctic (Tarnocai et al., 2007; Figure 33.31). Most of these soils are located in the Mackenzie River Valley and the Hudson Bay lowlands of Canada. In general, Histels mostly occur in the Boreal, Subarctic, and Low Arctic regions. Histels are commonly associated with palsas (a peaty permafrost mound containing a core of alternating layers of segregated ice and peat or mineral soil), peat plateau, peat hummocks, and low- and high-centered lowland polygons. These soils have been discussed fully by Zoltai and Tarnocai (1971), Tarnocai (1972, 1973), Zoltai and Tarnocai (1974, 1975), Everett (1979), and Bockheim et al. (2004).

Histels are divided into five great groups, including the Folistels, Glacistels, Fibristels, Hemistels, and Sapristels. With the exception of the Glacistels, these great groups follow the suborders in the Histosol order (Section 34.2). The Glacistels contain a glacic layer within 50 cm of the surface that is 30 cm or more thick and contains 75% or more ice (by volume).

33.6.3.2 Turbels

Turbels are mineral soils that occur in areas with patterned ground. Patterned ground is a general term for any ground surface with a discernibly ordered, more or less symmetrical, morphological pattern of ground and, where present, vegetation (Washburn, 1980). These soils show marked influence of cryoturbation (Figure 33.32b) and occur throughout the circumpolar regions. They are the dominant suborder and account for more than 57% of the Gelisols mapped in the circumarctic (Figure 33.31). Field and laboratory data for these soils are contained in publications by Douglas and Tedrow (1960), Tedrow et al. (1968), Tedrow (1970), Zoltai and Tarnocai (1974), Pettapiece (1975), Tarnocai and Smith (1992), Bockheim and Hinkel (2007), and Simas et al. (2008).

Most horizons and layers within the active layer of Turbels are strongly affected by cryoturbation. Turbels commonly contain irregular or broken horizons, involutions, organic matter that

usually accumulates on the surface of the permafrost, oriented rock fragments, and silt caps and silt-enriched subsoil horizons. Permafrost occurs within 200 cm of the soil surface. These soils are differentiated into seven great groups that link them with other orders not containing permafrost, including the Histoturbels (40%–80% organic materials by volume in the upper 50 cm), Aquiturbels (aquic conditions), Anhyturbels (anhydrous conditions) (anhydrous conditions refer to soils of cold deserts and other areas with permafrost [often dry permafrost] and low precipitation [usually <50 mm year⁻¹ water equivalent]. Anhydrous soil conditions are similar to the aridic and torric soil moisture regimes except that the soil temperature is <0°C [Soil Survey Staff, 2010]), Molliturbels (mollic epipedon), Umbriturbels (umbric epipedon), Psammoturbels (sandy texture), and Haploturbels (other Turbels).

33.6.3.3 Orthels

Orthels are mineral soils containing permafrost within the upper 100 cm, but they lack cryoturbation (Figure 33.32c). These soils comprise <3.6% of the Gelisols mapped in the circumarctic and occur primarily in areas with dry permafrost such as floodplains and the dry valleys of Antarctica. They are divided

into great groups that parallel the Turbels, that is, Historthels, Aquorthels, etc. Subgroups within each great group of Gelisols are listed in Table 33.27.

33.6.4 Cryopedogenic Processes

Cryopedogenic processes that lead to gelic materials are driven by the physical volume change of water to ice, moisture migration along (1) thermal, (2) hydrostatic pressure, (3) solute concentration, and (4) electrical potential gradients in the frozen (or unfrozen) system (Marion, 1995), or thermal contraction of the frozen material by continued rapid cooling. These processes include freezing and thawing, cryoturbation, frost heaving, cryogenic sorting, thermal cracking, and ice segregation (Tedrow, 1977; Washburn, 1980; Figure 33.33).

It should be emphasized that cryopedogenic processes are soil-forming processes characteristic of soils with permafrost and should not be viewed as operating against the other soil-forming processes in lower latitude soils; rather, they are distinctive processes producing horizons and properties that are uncommon to other soil orders (Bockheim et al., 2010). Processes common to the other soil orders operate in Gelisols but at a lesser magnitude because of the dominance of cryopedogenic processes.

33.6.5 The Pedon as a Basic Soil Unit

The pedon is the basic soil unit for sampling in *Soil Taxonomy* (Soil Survey Staff, 1999); it is an especially important concept for describing, classifying, and sampling Gelisols. The pedon is defined so as to encompass the full cycle of patterned ground

Cryopedogenic processes: Effects on soil morphology
FIGURE 33.33 Conceptual framework showing the interrelationships of the effects of cryopedogenic processes on development of specific fabric types in Gelisols. (Revised from Fox, C.A. 1994. Micromorphology of permafrost-affected soils, p. 51–62. *In* J.M. Kimble and R.J. Ahrens (eds.) Proc. Meet. Classif. Correl. Manage. Permafrost-Affected Soils. USDA-SCS, National Soil Survey Center, Lincoln, NE. With permission.)

with a 1 or 2 m linear interval or a half cycle with a 2–7 m cycle (Figure 33.34a). This interval is suitable for most patterned ground features such as earth hummocks, circles, nets, and nonsorted polygons. In the case of large-scale (>7 m) ice-rich polygons, such as those that occur along the Alaskan Coastal Plain, two pedons are delineated: one within the center of the polygon and the other within the ice wedge (Figure 33.34b).

If no patterned ground exists, the pedon is arbitrarily selected but approximates about 1 m² in area.

Scaled sketches of a pedon showing soil horizons, including patches of cryoturbated material, should be drawn on graph paper in the field, or digital images should be taken and the horizons annotated directly on the image (Figure 33.29). Samples should be collected from each horizon across the pedon and composited for subsequent laboratory characterization. In the case of highly cryoturbated soils, the areal percentage of each horizon is reported in soil descriptions rather than depth intervals (Kimble et al., 1993).

33.6.6 Historical Approaches to Classification of Permafrost-Affected Soils

Tedrow (1977) provided a comprehensive review of early approaches to classification of soils in the cold regions, emphasizing the zonal systems. Of the soil taxonomic systems used today, only the approaches of Canada (Agriculture Canada Expert Committee on Soil Survey, 1987), the United States (Soil Survey Staff, 2010), and *World Reference Base (WRB) for Soil Resources* (2006) recognize soils with permafrost in a separate order (Table 33.27).

(a)

(b)
FIGURE 33.34 The pedon concept as it applies to Gelisols and patterned ground form, including (a) a nonsorted circle (From Tarnocai, C. and Smith, C.A.S., The formation and properties of soils in the permafrost regions of Canada, in: D.A. Gilichinsky (ed.), *Proceedings of the First International Conference on Cryopedology*, Russian Academy of Science, Pushchino, Russia, 1992. With permission.) and (b) a large-scale, low-centered polygon. (From Bockheim, J.G., L.R. Everett, K.M. Hinkel, F.E. Nelson, and J. Brown. 1999. Soil organic carbon storage and distribution in arctic tundra, Barrow, Alaska. Soil Sci. Soc. Am. J. 63:934–940. With permission.) The Canadian soil horizon nomenclature is used, where Ah = A, Bmy = Bwjj, Cy = Cjj, and Cz = Cf in *Soil Taxonomy*.

Whereas permafrost-affected soils are identified as Gelisols (from the Greek word, gelid, meaning very cold) in *Soil Taxonomy*, they are called Cryosols (from the Greek word, kraios, meaning cold or ice) in the other two systems. The Canadian and U.S. systems divide permafrost-affected soils into three categories: organic soils, cryoturbated mineral soils, and other mineral soils. The soils are further delineated on the basis of key properties that link them with soils of lower latitudes. In the WRB, the Cryosol soil group is divided into 16 soil units. Fifteen suffix qualifiers are used to link Cryosols with soils of lower latitudes.

33.6.7 Properties of Gelisols

Gelisols/Cryosols encompass a vast array of soils in terms of chemical and mineralogical properties. However, with the exception of the Histels, Gelisols are uniform in terms of physical and thermal properties.

33.6.7.1 Macromorphology

The most common macroscopic soil features are due to cryoturbation and include irregular or broken horizons and incorporation of organic matter in lower horizons, especially along the top of the permafrost. Oriented stones and displacement of soil materials are common in Gelisols. Freezing and thawing produce granular and platy structures in surface horizons and blocky, prismatic or massive structures in subsurface horizons. The massive structure is due to cryostatic pressure and desiccation that develop when the two freezing fronts, one from the surface and the other from the permafrost, merge during freeze back in the autumn. The perennially frozen layer commonly contains ground ice in the form of segregated ice crystals, vein ice, ice lenses and wedges, and thick ground ice.

The granular, platy, or blocky structures of the surface mineral horizons are also the result of cryopedogenic processes such as the freeze–thaw process and vein-ice formation (ice segregation process). The subsurface horizons often have massive structures and are associated with higher bulk densities, especially in fine-textured soils.

Almost all Gelisols contain ice in the form of crystals, lenses, layers (vein ice), wedges, or massive ground ice, often to a thickness of several meters. Soil texture is one of the factors controlling ice content in mineral soils with fine-textured Gelisols generally having higher ice contents than coarse-textured soils. Coarse-textured soils often have a relatively low ice content; however, they may contain ice wedges in the form of polygons. Histels have an ice content of 60%–90% on a volume basis (Zoltai and Tarnocai, 1975).

The active layer that is subject to annual thawing and refreezing lies above the permafrost and not only supports biological life, but also protects the underlying permafrost. The thickness of the active layer is controlled by soil texture and moisture, thickness of the surface organic layer, vegetation cover, aspect, and latitude.

Dilitancy, often confused with thixotropy, is common in soils with high silt content, greatly affects the trafficability of the soil, and is frequently present during the thaw period. Dilitancy is a property of granular masses expanding due to the increase of space between rigid particles upon displacement of the particles. When dilitant soils dry out, a characteristic vesicular porosity develops. Salt crusts, patches, and pans are common in polar desert soils of the high arctic and cold desert soils of Antarctica (Tedrow, 1977; Bockheim, 1997).

33.6.7.2 Micromorphology

When viewed in thin sections, Gelisols contain a variety of fabrics resulting from desiccation and displacement due to alignment, rotation, sorting, and inclusions (Figure 33.33). These features are accompanied by planar voids, cracks, and vesicles during pore formation. More specifically, the fabric of Gelisols varies from granular (granic and granoidic) in the surface horizons to mainly porphyroskelic with fragmic and fragmoidic components in subsurface mineral horizons (Pawluk and Brewer, 1975; Fox, 1985; Smith et al., 1991; Schaefer et al., 2008). The micromorphology of Gelisols can show evidence of matrix displacement and movement, with resultant reorganization of skeleton grains into circular or elliptical patterns, producing an orbicular fabric (Fox and Protz, 1981). Ice lensing and vein ice development lead to the formation of lenticular fabrics, while cryoturbation and cryodesiccation can lead to granic or granoidic fabrics (Smith et al., 1991). In addition, suscitic and conglomeric fabrics also are common in Gelisols (Fox and Protz, 1981).

33.6.7.3 Thermal Characteristics

Soil temperatures for a Gelisol located north of the arctic treeline in Canada are shown in Figure 33.35. The unique thermal signature that separates Gelisols from all other soils is the presence of a perennially frozen layer, usually below 50 cm. Because of this frozen layer, Gelisols have a steep vertical temperature gradient. If these soils are associated with certain types of patterned ground, the horizontal temperature gradient can also be large. For example, in the case of Gelisols associated with earth hummocks, the soil temperature at the center of the hummock can decrease from 12°C at the surface to 0°C at 50 cm during the summer months. Soil temperatures at comparable depths under the interhummock depression, <1 m away and at equivalent depths, can be 5°C–7°C lower (Tarnocai and Zoltai, 1978).

33.6.7.4 Physical and Chemical Characteristics

Histels contain weakly to well-decomposed moss, sedge, woody, and amorphous organic material. The pH of these soils ranges from 2.5 to 7.0 (Table 33.28). Histels derived from moss peats (Fibristels) tend to have lower pH values than other organic soils with permafrost. Turbels and Orthels developed from calcareous parent materials have a pH_{CaCl_2} of 7 and a high base saturation. On the other hand, where these soils are developed from acidic parent materials, $pH_{CaCl_2} < 5.5$.
FIGURE 33.35 Soil temperature variation in Gelisols from (a) Auyuittuq National Park, Baffin Island, Canada (66°23′30″N, 65°29′20″W) and (b) Lake Hazen, Quttinirpaaq National Park, Ellesmere Island, Canada (81°49′15″N, 71°33′17″W) during 1999. (From Tarnocai, C. 2008. Arctic permafrost soils, p. 3–16. *In* R. Margesis (ed.) Permafrost soils. Soil Biology Series. Vol. 16. Springer-Verlag, Berlin, Heidelberg, Germany. With permission.)

Anhyturbels and Anhyorthels in polar and cold deserts often have high salt contents and electrical conductivities. Although these soils have many features common to Aridisols (Section 33.10), they have patterned ground, dry permafrost in the upper meter over ice-cemented permafrost, and show evidence of thermal cracking (Bockheim, 1997).

Gelisols, especially the Histels and Turbels, often contain large amounts of organic C in the upper m, with values commonly ranging from 3 kg C m⁻³ in Haplorthels to over 100 kg C m⁻³ in Sapristels and averaging about 50 kg C m⁻³ (Bockheim et al., 1999, 2004; Tarnocai et al., 2007). This is similar to Histosols of other regions (Section 33.2). Less than half of the organic C in Turbels is in the active layer, with the remainder in the upper 30–50 cm of permafrost (Bockheim et al., 1997). Much of this organic carbon exists below 1 m, the depth to which carbon stores are normally reported.

The particle size distribution of Gelisols varies from clayey to coarse gravelly sand. The composition of the fine-earth fraction is commonly dependent on the composition and age of the parent materials.

33.6.8 Special Problems in Managing Gelisols

Gelisols present special problems in terms of management, not only because of frost churning, heaving, sorting, and cracking, but also because melting of segregated ice following a disturbance to the thermal regime leads to subsidence, or thermokarst. To preserve the integrity of structures (buildings, roads, and pipelines) in permafrost soil, it is important to maintain the negative thermal balance of the soil. This is achieved by using special construction methods. For agricultural development, it is important to determine the ice content of the soil; otherwise, after clearing of the land or within a few years after cultivation begins, severe subsidence and thermokarst can develop (Péwé, 1982).

33.6.9 Global Warming and Trace Gas Emissions

General circulation models (GCMs) predict that with a projected twofold increase in atmospheric CO_2 by the year 2050, the mean air temperature of the Earth's surface could increase by 1.5°C–4.5°C (Maxwell and Barrie, 1989); however, warming at the high northern latitudes could be on the order of 4°C–5°C. Indeed, sea ice variations over the past several decades are compatible with a distinct warming of air temperatures in the arctic, especially during the winter and spring (Arctic Climate Impact Assessment, 2004). In addition, permafrost temperatures in northernmost Alaska have increased by 2°C–4°C during the last few decades (Lachenbruch and Marshall, 1986).

As mentioned previously, Gelisols are large C sinks. There is concern that warming in the circumpolar regions could increase the thickness of the active layer and enhance heterotrophic respiration, releasing additional CO_2 to the atmosphere (Oechel and Billings, 1992; Shaver et al., 1992; Waelbroeck et al., 1997), and Gelisols would become a C source. However, Bockheim (2007) has pointed out that continued warming in the arctic could accelerate cryoturbation and enable some soils to store more organic C at depth than at present, thereby mitigating some of the loss of CO_2 to the atmosphere from increased soil respiration.

33.6.10 Human-Caused Disturbances

Arctic regions contain vast energy reserves, including fossil fuels (coal, oil, and gas), biomass, and hydropower. The extraction of fossil fuels and minerals and deforestation may have dramatic long-term effects on arctic ecosystems as they have a low resistance and resilience to disturbance (Reynolds and Tenhunen, 1996). As the world's population continues to expand, there will be increased pressure for development at the high latitudes. For example, Siberia already contains several cities that were developed in permafrost and have in excess of 500,000 inhabitants.

The circumarctic contains numerous indigenous people who are dependent on the terrestrial and marine ecosystems for

food, fuel, and shelter. Special efforts must be made to ensure that these ecosystems remain sustainable. The polar regions are less diverse biologically than other life zones. However, ancient (~2.5 million years old) permafrost contains viable microorganisms that may give clues to the evolution of microbes (Gilichinsky, 1993).

33.7 Vertisols

Randal J. Southard

Steven G. Driese

Lee C. Nordt

33.7.1 Introduction

Vertisols are clayey soils that exhibit significant volume change due to shrink and swell processes as the soil dries and wets. Most Vertisols have smectitic mineralogy, but Vertisols with mixed or kaolinitic mineralogy also occur. The intrinsic shrink/swell behavior is the dominant soil-forming process of Vertisols and results in significant close-range spatial and temporal variability of soil properties, possibly more so than in any other soil order. As a result, Vertisols are often difficult to manage for agricultural, natural resource, and engineering applications. A substantial body of information about Vertisols exists in the literature, including summaries (e.g., Coulombe et al., 2000; Blokhuis, 2002), and more in-depth discussions about specific aspects of Vertisols (e.g., Ahmad, 1983; Probert et al., 1987; Wilding and Puentes, 1988; Kimble, 1991; Ahmad and Mermut, 1996; Coulombe et al., 1996b).

33.7.2 Distribution and Formation

Geographically, Vertisols occur in more than 100 countries and occupy 309 Mha (10^6 ha), which corresponds to about 2% of the ice-free land area (Table 33.1; Figure 33.36; USDA-NRCS, 2009). Globally, Vertisols are most extensive in India (80 Mha), Australia (70 Mha), and Sudan (50 Mha), followed by the United States (18 Mha), Ethiopia (13 Mha), and China (12 Mha) (Dudal and Eswaran, 1988; Isbell, 1991; Blokhuis, 2002).

In the United States, Vertisols are reported in 25 states and territories (Coulombe et al., 1996b, 2000), primarily west of the Mississippi River and in the Black Belt region of the southern states. Vertisols are most extensive in Texas (6.5 Mha), South Dakota (1.5 Mha), California (1 Mha), and Montana (0.6 Mha). The remaining states each have less than 0.25 Mha of Vertisols and vertic intergrades.

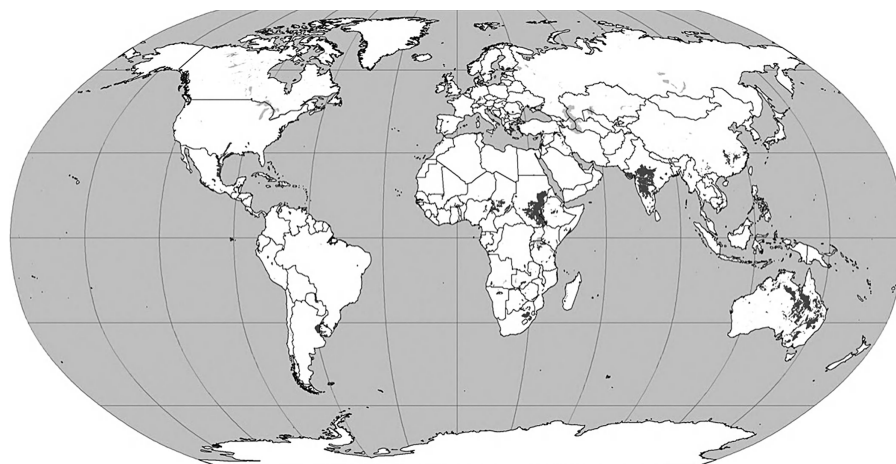
Vertisols are formed from a wide variety of parent materials of varying age and under a wide range of climatic conditions (Coulombe et al., 1996a, 1996b). A common attribute is a soil-forming environment that favors preservation of silica and basic cations and that produces episodic or periodic wetting and drying to allow cracks to form. Most Vertisols occur


FIGURE 33.36 Global distribution of Vertisols. (Courtesy of USDA-NRCS, Soil Survey Division, World Soil Resources, Washington, DC, 1998.)

on shallow slopes in uplands and on a variety of alluvial landforms. Natural vegetation of Vertisols is typically grassland and savanna, probably because most woody plant roots cannot survive shearing during wetting and drying, but mixed/deciduous forested and scrub/shrub can occur, depending on the ecological succession of the vegetation and human impact.

33.7.3 Morphology

33.7.3.1 Color

In general, Vertisols are dark in color, particularly in the upper horizons. Typically, they exhibit a moist Munsell value of 3 or less and chroma of 2 or less in the matrix, and have hues of 7.5YR or yellower. The dark colors are generally attributed to the close association of organic matter with clay minerals and to various compounds of Mn, Fe, and Ti (Ahmad and Mermut, 1996). Vertisols with black, gray, brown, or red pigmentation have been reported in various regions of the world. In the most recent *Keys to Soil Taxonomy* (Soil Survey Staff, 2010), dark Vertisols are considered the norm; soil color differentiates Chromic subgroups, which require a value of 4 or more (moist), or 6 or more (dry), or a chroma of 3 or more. The chroma requirement does not apply to

the subgroup of Aquerts. Lighter soil colors are usually associated with the accumulation of calcium carbonate, gypsum, or more soluble salts, especially in subsurface horizons. Reddish redox concentrations can occur in poorly drained Vertisols; reddish matrix colors and high chroma are often associated with Vertisols on better drained landscapes, and in less humid climates, and possibly in Vertisols formed from parent material with low Mn content.

33.7.3.2 Texture

Vertisols are fine-textured soils. In general, Vertisols must have at least 30% clay in the fine-earth fraction in the upper 50 cm or to a densic, lithic, or paralithic contact, a duripan, or a petrocalcic horizon if any of those features is shallower (Soil Survey Staff, 2010). Clay content of Vertisols can be as high as 90%, particularly for those derived from pyroclastic deposits. Soils that do not meet the clay content requirements, or that do not exhibit other required properties (slickensides or wedge-shaped peds, and cracks, described below), but that exhibit considerable shrink/swell activity as measured by the coefficient of linear extensibility (COLE), often are classified as vertic intergrades to other soil orders. Particle size distributions for selected Vertisols are shown in Table 33.29.

TABLE 33.29 Particle Size Distribution of Selected Vertisols Formed from a Wide Variety of Parent Materials

Regions	% Sand 2.00–0.50 mm	% Silt 0.50–0.002 mm	% Clay <0.002 mm	References
Australia	16.0 (2.5)	33.6 (3.7)	50.3 (5.5)	Boettinger (1992)

Uruguay	26.3 (5.6)	27.0 (8.1)	46.7 (13.3)	Lugo-Lopez et al. (1985)

Data are reported as mean (sd).

33.7.3.3 Differentiating Physical Properties and Features

In addition to the clay content requirements, Vertisols must exhibit significant shrink/swell characteristics to develop diagnostic soil structure and features in the soil profile. Evidence of shrink/swell behavior includes slickensides or wedge-shaped aggregates with the long axis inclined at 10°–60° from the horizontal (Soil Survey Staff, 2010). Slickensides are more or less planar features that exhibit shiny and grooved surfaces at the interface of the peds (Figure 33.37) that indicate soil movement and shearing. The presence of slickensides in a soil horizon is typically indicated by the morphological horizon designation, Bss. Wedge-shaped aggregates are soil structural units that generally result from limited formation of slickensides bounding ped surfaces (Figure 33.38). The presence of cracks (Figure 33.39) that open and close in response to drying and wetting is also a requirement for Vertisols (Soil Survey Staff, 2010).

Gilgai and diapir are other features that may be present in Vertisols. Gilgai (Figure 33.40) is an Australian aboriginal term used to describe microtopography (Figures 33.41 and 33.42) that
FIGURE 33.37 The glossy slickensides show evidence of subsoil shrink-swell and shearing. (Photograph from Eswaran et al., 1999).
FIGURE 33.38 Wedge-shaped peds are a result of subsoil shearing in many Vertisols. The bar represents 5 cm. (Photograph courtesy of Susan B. Southard, USDA-NRCS).

FIGURE 33.39 Cracks that open and close periodically are a required morphological feature of Vertisols. These cracks range from about 1 to 6 cm wide. (Photograph from Eswaran et al., 1999).

FIGURE 33.40 Vertisol microtopography (gilgai) is especially evident during the wet season. (Photograph from Eswaran et al. 1999).

FIGURE 33.41 Cross-section of a Vertisol exposed in a trench. Darker-colored bowls, or microlows, are evident on the left and right sides of the exposure. A lighter-colored diapir, or microhigh, is visible between the bowls to the right of the tape measure. Strings have been used to delineate regions of distinctive morphology. The tape measure is 180 cm long (Photograph from Eswaran et al., 1999).
FIGURE 33.42 Schematic representation of Vertisol morphology and horizon arrangement. (From Coulombe, C.E., L.P. Wilding, and J.B. Dixon. 1996b. Overview of Vertisols: Characteristics and impacts on society. Adv. Agron. 57:289–375. With permission.)

consists of mounds (microhigh), shelves (intermediate), and depressions (microlow), either in circular, linear, or complex patterns. Prior to 1992, *Soil Taxonomy* used gilgai as a differentiating characteristic of Vertisols, but, that criterion was eliminated because not all Vertisol landscapes have gilgai. Diapir, also called mukkara in Australia, in this context was adopted from geology terminology, where the term is used to describe large-scale intrusions of ductile material (often mud or salt) into more rigid, surrounding rock. In Vertisols, a diapir is a smaller-scale intrusion of soil material that penetrates from the subsoil through the upper layers and can be identified by a contrast in color and/or texture. Diapirs may occur independent of gilgai; however, when gilgai are present, the tip of the diapir coincides with the mound or microhigh.

33.7.4 Genesis

The dominant processes that lead to the characteristic properties of Vertisols is shrinking and swelling induced by changes in soil water conditions. The shrink/swell action can be observed from macroscopic to submicroscopic scales of resolution (Figure 33.43). The shrink/swell phenomena are clearly related to the changes in the interlayer spacing of expansible phyllosilicate minerals, principally smectites, by sorption and desorption of interlayer water. However, changes in the interlayer spacing of smectites contribute only 10%–30% of the change in volume when saturated with Ca (Greene-Kelly, 1974; Tessier, 1984). Tessier (1984) reported that the type of microstructure, for example, crystallite, domains, or quasicrystals (Figure 33.43) and the surface area of the clay mineral phases govern the shrink/swell potential. The microstructure and the porosity accommodate the changes in water content and potential of the clay-water systems. Other factors affecting shrink/swell phenomenon include particle rigidity, stress history, predominance of cations present on the exchange sites (e.g., Na vs. Ca), the electrolyte concentration of the soil solution, and the amount and location of the charge in the clay mineral crystallographic structure, which may cause variation in the structural organization and the interlayer distance among smectites.

Tessier (1984), Quirk (1994), and Coulombe et al. (1996a, 1996b) extensively reviewed the models and factors involved in shrink/

swell processes. According to Coulombe et al. (1996b), the application of the Coulomb–Mohr theory of shear failure constitutes the best model to account for the formation and occurrence of features and structure in Vertisols. Shear failure is more likely to occur under moist or wet than dry conditions, since a lower normal stress is required to promote shear failure. Even though shrink/swell processes are a common phenomenon among Vertisols, other pedogenic processes also occur, such as accumulation of salts (e.g., salic, natric, calcic, and gypsic great groups), silica (duric great group), and depth of saturation by water (epi and endo great groups).

33.7.5 Classification

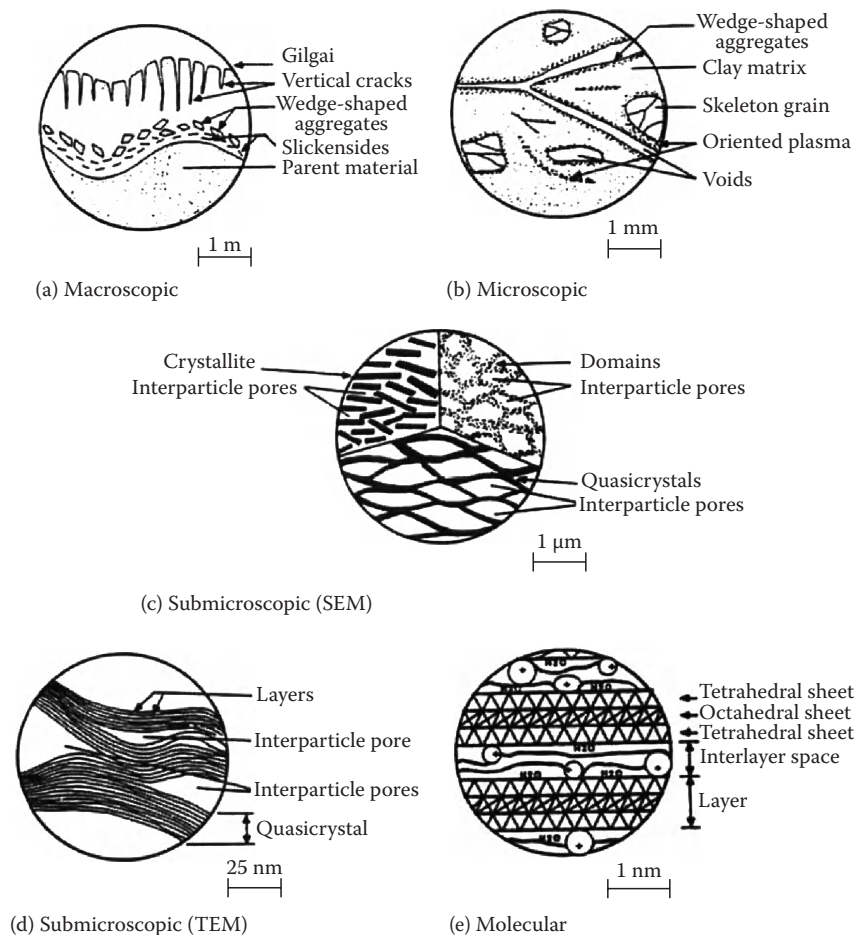
Vertisol is the widely accepted term to designate fine-textured soils with extensive shrink/swell behavior. The term originates from *vertere* (L.), meaning to churn or turn over and *sol* for soils (Dudal and Eswaran, 1988). Coulombe et al. (1996b) discussed the history and evolution of the Vertisol order in the U.S. soil classification systems. Vertisols were first introduced as a soil order in the *7th Approximation* (Soil Survey Staff, 1960), and differentiating criteria were subsequently modified in *Soil Taxonomy* (Soil Survey Staff, 1975, 1999). Prior to the *7th Approximation*, most Vertisols were identified as Grumosols, Regosols, Rendzina, or Alluvial soils (Soil Survey Staff, 1975). In 1960, Vertisols were the first order in the key and were differentiated on the basis of clay content, cation exchange capacity, cracks, and evidence of shrink–swell in the form of gilgai, slickensides, or wedge-shaped aggregates. Two suborders, Aquerts and Usterts, were identified, and an important property for identifying great groups was the presence of a self-mulching surface horizon (Figure 33.44; "Grumic" great groups, e.g., Grumaquerts) or of a platy or massive surface crust ("Mazic" great groups, e.g., Mazusterts). In the first edition of *Soil Taxonomy* (Soil Survey Staff, 1975), Vertisols were placed as the fourth order in the key, subgroups keyed in the sequence: Xererts, Torrerts, Uderts, and Usterts (no Aquerts), and great groups were identified on the basis of soil color, not grumic or mazic properties (e.g., Chromoxererts, with moist soil chroma ≥1.5 in the upper 30 cm, otherwise Pelloxererts). Revisions based on the efforts of ICOMERT (the International Committee on the Classification of Vertisols) added the Aquerts


FIGURE 33.43 Shrink-swell features depicted at various scales of resolution. (From Coulombe, C.E., L.P. Wilding, and J.B. Dixon. 1996b. Overview of Vertisols: Characteristics and impacts on society. Adv. Agron. 57:289–375. With permission.)

and Cryerts suborders and included some of the subsurface diagnostic horizons as criteria for differentiation of great groups (Soil Survey Staff, 1999).

The Vertisol order currently keys out as the sixth order, based on the following (Soil Survey Staff, 2010):

Other soils that have:

1) A layer 25 cm or more thick, within 100 cm of the mineral soil surface, that has *either* slickensides *or* wedge-shaped peds that have their long axes tilted 10 to 60 degrees from the horizontal; *and* 2) A weighted average of 30 percent or more clay in the fine-earth fraction either between the mineral soil surface and a depth of 18 cm or in an Ap horizon, whichever is thicker, *and* 30 percent or more clay in the fine-earth fraction of all horizons between a depth of 18 cm and either a depth of 50 cm or a densic, lithic, or paralithic contact, a duripan, or a petrocalcic horizon if shallower; *and* 3) Cracks that open and close periodically.

The order is subdivided into 6 suborders, 24 great groups, and 158 subgroups (Soil Survey Staff, 2010; Table 33.30). The suborders are identified on the basis of aquic conditions, cryic soil temperature regime, and the frequency and duration of soil cracking. The cracking criterion allow inferences about the soil moisture regime (as implied by the suborder names), but soil moisture regimes in Vertisols are not well characterized due to cracking and slow permeability when wet, leading to heterogeneous wetting and drying of the soils and preferential bypass flow. Because

TABLE 33.30 Listing of Suborders, Great Groups, and Subgroups for the Vertisol Order

Suborders	Great Groups	Subgroups
Aquerts	Sulfaquerts	Salic, Sulfic, Typic
	Salaquerts	Aridic, Ustic, Leptic, Entic, Chromic, Typic

of low permeability and water conductance via bypass flow along macrovoids, Vertisols rarely saturate in their entirety (Jacob et al., 1997; Nordt and Driese, 2009). The great group categories reflect additional dominant soil processes and resulting diagnostic horizons, and subgroups represent intragrade or intergrade concepts toward other soil orders or categories. Vertisols are not required to have a specific diagnostic horizon, although many have mollic epipedons and cambic horizons.

Vertisols are also recognized in other international soil classification systems such as FAO–UNESCO (1988, 1998) and the World Reference Base (WRB) for Soil Resources (IUSS Working Group WRB, 2007) and the French systems (CPCS, 1987; Baize and Girard, 1996). Some variations in the criteria used to differentiate Vertisols may occur from one classification system to another, but the *Soil Taxonomy* criteria for Vertisols (no vertic horizon) and the following WRB criteria (IUSS Working Group WRB, 2007) for a vertic horizon and for identification of Vertisols are essentially the same.

33.7.5.1 Vertic Horizon

The vertic horizon (from Latin vertere, to turn) is a clayey subsurface horizon that, as a result of shrinking and swelling, has slickensides and wedge-shaped structural aggregates. Diagnostic criteria (1) contains 30% or more clay throughout; (2) has wedge-shaped structural aggregates with a longitudinal axis tilted between 10° and 60° from the horizontal; (3) has slickensides; and (4) has a thickness of 25 cm or more.

Vertisols key out as the sixth Reference Soil Group as follows: Other soils having (1) a vertic horizon starting within 100 cm of the soil surface; and (2) after the upper 20 cm have been mixed, 30% or more clay between the soil surface and the vertic horizon throughout; and (3) cracks that open and close periodically.

33.7.6 Mineralogical Properties

Most Vertisols are dominated by smectitic mineralogy. However, Vertisols containing abundant kaolinite, illite, halloysite, hydroxy-interlayered smectite, or a combination of interstratified clay minerals are also found in various regions of the world (Coulombe et al., 1996a). Recognition of Vertisols with these mineralogical characteristics has caused geoscientists to reconsider the Vertisol paradigm and the mechanisms involved in the shrink/swell processes of soils that are not dominated by smectite. As discussed earlier, shrink/swell behavior includes expansion and collapse of interlayer space, but also involves changes in microstructure and porosity associated with changes in water content and potential (Tessier, 1984; Wilding and Tessier, 1988; Coulombe et al., 1996a).

The smectites that dominate most Vertisols tend to concentrate in the fine clay fraction and contribute to high particle surface area and shrink–swell potential. Characteristics of smectites in Vertisols, which may also apply to other clay minerals and other soil orders, include (1) relatively high thermodynamic stability, (2) high layer charge (>0.45 per half unit cell), which may be as high as vermiculite or illite and may impact the availability of some ions such as K and NH_4, and (3) a high Fe content in some crystallographic structures such as nontronite or beidellite, particularly when derived from basaltic parent materials containing abundant ferromagnesian minerals (Coulombe et al., 1996a). A CEC/clay ratio ≥0.60 is typical of soils in the smectitic mineralogy class at the family taxonomic level (a CEC/clay ratio ≥0.60 identifies the "superactive" CEC activity family class [Soil Survey Staff 2010], which suggests that the clay fraction is dominated by smectites).

33.7.7 Chemical Properties

33.7.7.1 pH

Vertisols are commonly neutral to alkaline in reaction (Table 33.31), given that the majority are derived from calcareous or base-rich parent materials. However, acidic Vertisols (Ahmad, 1985) do exist and are recognized as Dystric great groups of the Aquerts, Uderts, and Usterts (pH values of 4.5 or less in 0.01M $CaCl_2$ [5.0 or less in 1:1 water] and electrical conductivity less than 4.0 dS m^{-1}). Some Vertisols have a sulfuric horizon with a pH or 3.5 or less (Soil Survey Staff, 2010) produced by the oxidation of sulfides and resulting formation of sulfuric acid, or they contain sulfidic materials that can oxidize and acidify the soil (e.g., Sulfaquerts).

33.7.7.2 Cation Exchange Capacity and Exchangeable Cations

Cation exchange capacity (CEC) of Vertisols generally ranges from about 30 to about 60 cmol$_c$ kg^{-1} (soil) and depends on the amount and type of mineral phases and soil organic matter (SOM) present (Table 33.31). Calcium and Mg commonly are the

main exchangeable cations. In some cases, Na is an abundant exchangeable cation, and when exchangeable Na percentage (ESP) exceeds 15, particle dispersion and soil structure deterioration can occur. Particle dispersion can occur at ESP values less than 15 if soluble salts are absent and the resulting soil solution electrolyte concentration is low. The presence of soluble salts and gypsum can maintain solution electrolyte concentrations at high enough levels to prevent soil dispersion even at ESP values greater than 15. Under acidic conditions, Al and H may become more prevalent in the soil solution and replace exchangeable Ca and the other base cations. An increase in the concentration of exchangeable Al and H and a decrease in CEC indicate that chemical weathering has occurred, via dissolution of primary and secondary (clay) minerals (Ahmad, 1985).

33.7.8 Soil Biochemical Properties

Biochemical properties are most strongly influenced by the quantity and type of organic matter, and land use (Table 33.32). Generally, organic C content ranges from 3 to 60 g kg^{-1}, but most commonly from 3 to 35 g kg^{-1} (Coulombe et al., 1996a), and varies with (1) climatic conditions (higher under more humid and cooler regimes); (2) microtopography (higher in microlows than in microhighs; Kunze and Templin, 1956; Wilding and Tessier, 1988; Nordt et al., 2004); (3) depth (generally decreases with depth in the soil profile, which refutes the argument that complete self-mixing occurs in Vertisols, or at least indicates that the rate of mixing is slower than the rate of soil organic C accumulation and redistribution; Wilding and Tessier, 1988; Southard and Graham, 1992; Coulombe, 1997); and (4) tillage (higher in noncultivated than in cultivated areas; Kunze and Templin, 1956; Skjemstad and Dalal, 1987; Coulombe, 1997; Chevallier et al., 2000; Nordt and Wilding, 2009).

Soil organic matter has some influence on soil color, but black Vertisols may contain as little as 3 g kg^{-1} organic C. The contribution of soil organic matter to the dark color is the result of strong clay–organic complexes in which smectites are coated

with humic materials in the presence of Ca (Singh, 1954, 1956). The resistance to degradation is due to this smectite–Ca–organic complex, rather than due to the recalcitrant chemical composition of the organic material (Skjemstad et al., 1986; Skjemstad and Dalal, 1987).

The C/N ratio generally ranges from 10 to 25 (Table 33.32). Microbial biomass may represent up to 5% of total organic C (Jocteur Monrozier et al., 1991). Polysaccharides and fungal hyphae tend to be concentrated at interparticle positions in the domains and quasicrystals of the clay minerals (Chenu, 1989; Chenu and Jaunet, 1990). Total P ranges widely (Table 33.32), mostly as a function of parent material composition, but may also reflect organic forms of P that vary as a function of SOM content and soil management.

Loss of organic C can occur rapidly after a change in land use from native conditions to cultivation. After a few decades or more of continuous cultivation, loss of organic C can be significant (Skjemstad et al., 1986; Skjemstad and Dalal, 1987; Puentes, 1990; Coulombe, 1997; Nordt and Wilding, 2009), but the trend can be reversed, at least to some degree, when cultivated fields are allowed to return to native conditions (Chevallier et al., 2000).

33.7.9 Physical Properties

33.7.9.1 Moisture Retention and Shrink/ Swell Behavior

Soil moisture conditions are especially important in Vertisols because they dominate the physical properties and shrink/swell behavior. Due to the clay content, Vertisols exhibit high water retention characteristics at all water potentials (Table 33.33).

TABLE 33.33 Physical and Mechanical Characteristics[a] of Selected Vertisols from a Wide Array of Parent Materials

n/a, Data not available.

[a] Data are reported as mean (sd).

Soil water content varies considerably depending on the amount and kind of clay, climatic conditions, and land use.

Shrink/swell behavior places major constraints on the management of Vertisols. Under normal field conditions, most of the volume change occurs at water potentials >−1.5 MPa (Yule and Ritchie, 1980a; Wilding and Tessier, 1988), but it is not clear whether volume change is isotropic (equidimensional) or anisotropic. Current knowledge suggests that individual undisturbed peds shrink and swell isotropically (Yule and Ritchie, 1980a; Cabidoche and Voltz, 1995). Yule and Ritchie (1980b) reported that shrinkage in large (73 cm diameter, 140 cm long) and small (10 cm diameter) cores of a Texas Vertisol was similar. However, under field conditions, Cabidoche and Voltz (1995) reported anisotropic volume change in a Vertisol from Guadeloupe (French West Indies) with slightly larger movements vertically than horizontally (anisotropy ratio ~0.8). They attributed the anisotropy to movement of the peds along oblique slickensides, which highlights the importance of spatial arrangement or geometry of the peds in a soil profile on shrink/swell behavior.

33.7.9.2 Bulk Density and Coefficient of Linear Extensibility

Bulk density values for selected Vertisols are presented in Table 33.33. Factors that influence bulk density include (1) water content, (2) clay content, (3) particle density of the mineral fraction, and (4) the method used to determine bulk density (e.g., core vs. clods). Bulk density is routinely used to estimate total porosity and other volumetric percentages and to assess structural conditions of soils. Bulk density should be coupled with morphological characteristics and other properties for a thorough assessment of soil structural conditions.

The coefficient of linear extensibility (COLE) is an index of soil shrinkage (Table 33.33). The COLE value is typically calculated from soil bulk densities measured at −0.033 and −1.5 MPa, assuming that soil shrinkage is isotropic [COLE = (bulk density dry/bulk density moist)$^{1/3}$ − 1]. COLE is correlated with total and fine clay contents, surface area, water retention at field capacity, and ESP (Anderson et al., 1973; Yule and Ritchie, 1980a; Yerima et al., 1989).

33.7.9.3 Consistence and Atterberg Limits

Consistence refers to "the degree and kind of cohesion and adhesion that soil exhibits, and/or the resistance of soil to deformation or rupture under an applied stress" (Schoeneberger et al., 2002). The consistence of Vertisols ranges from hard to extremely hard when dry, from friable to very firm when moist, and from moderately sticky and moderately plastic to very sticky and very plastic when wet. Vertisols exhibit very narrow ranges of consistence and soil water content favorable for workability and trafficability.

The Atterberg limits (liquid limit, plastic limit, and plasticity index; Chapter 3) are empirical tests used by geoscientists and engineers to determine the mechanical characteristics of a soil and are approximated by the soil consistence properties described above. Values for Vertisols are presented in Table 33.33. In general, values of Atterberg limits increase as the clay content increases and decrease in the order: smectite > illite > kaolinite.

33.7.9.4 Structure/Porosity and Related Properties

Soil processes such as gas exchange, heat transfer, water flow, and movement of solutes and organics are dependent on structure and porosity. Vertisols tend to form large pores (macro- and mesopores, i.e., cracks) during soil drying and shrinkage. These cracks have a profound impact on several soil processes. They allow oxygen at atmospheric partial pressure to penetrate to the depth of cracking, they allow greater nitrification rates than in the rest of the soil mass (Kissel et al., 1974), and they promote movement of water and solutes through preferential or bypass flow (Kissel et al., 1973, 1974; Bouma, 1983; Bouma and Loveday, 1988). Lin et al. (1996) reported, for a Texas Vertisol, that macropores (>0.5 mm effective diameter) and mesopores (0.06 to <0.5 mm effective diameter) contributed 89% and 10% of the water flow, respectively. Several soil properties influence infiltration rates (Table 33.34). In clayey soils that shrink and swell, hydraulic conductivity (K) does not meet the assumption of uniform flow in a homogenous soil (Darcy's law), so infiltration rates are often preferred over K to characterize water movement (Lin, 1995; Lin and McInnes, 1995). Nonetheless, infiltration rates can be highly variable in space and time and remain dependent on a variety of factors including land use and the method used to measure infiltration rate.

33.7.10 Land Use and Management Considerations

33.7.10.1 Natural Resources

33.7.10.1.1 Agriculture

For many regions of the world, Vertisols are highly productive and sustainable resources for various crop production systems, including a wide array of food and fiber crops. Nonetheless, Vertisols in developed and developing countries are subject to degradation due to intensive and/or inappropriate management practices. Soil properties may partially recover from the effects of cultivation, but it is unlikely that native conditions can be rejuvenated even after a restoration period of 20 years or more (Puentes, 1990; Coulombe, 1997; Chevallier et al., 2000; Nordt and Wilding, 2009). One of the difficulties in successfully managing Vertisols involves some limitations on technology transfer. Despite the common properties of high clay content, shrink/swell behavior, and cracking, many Vertisols require site-specific management for crop production (Ahmad and Mermut, 1996) due to variations in climate, soil chemistry, and cropping systems.

33.7.10.1.2 Wetlands

Vertisols, especially those on the wetter end of the climatic spectrum (i.e., Aquerts and Uderts), can potentially be used for the creation or restoration of wetland habitats (Chapter 20

of *Handbook of Soil Sciences: Resource Management and Environmental Impacts*). Besides the presence of hydric conditions, a requirement for successful establishment of desired wetland functions includes development of wetland hydrology and the presence of hydrophytic vegetation. The swelling of Vertisols when wet drastically reduces permeability and provides a mechanism to more easily manage surface waters to maintain hydric conditions, establish wetland hydrology, and provide an environment that favors hydrophytic vegetation.

33.7.10.2 Engineering

33.7.10.2.1 Environmental Engineering

Due to their extensive shrink/swell behavior, Vertisols are generally not suitable for solid waste and wastewater disposal. Water generally percolates too rapidly when the soils are dry and too slowly when the soils are wet. In either case, these conditions could contribute to contamination of surface and groundwater and result in potential environmental health hazards. For similar reasons, Vertisols that exhibit a permanent (endoaquic) or seasonally perched (epiaquic) water table would not be a suitable filter for wastewater disposal. Further, disposal facilities built on Vertisols are prone to damage by shrink/swell processes that can crack foundations or rupture pipes.

On the other hand, Vertisols can be used as constructed treatment wetlands for final disposal of tertiary effluent provided that wetland hydrology is maintained at saturation to enhance low soil permeability and to reduce groundwater recharge. Treatment wetlands are effective technologies for water quality improvement of various wastewaters as well as being beneficial for wildlife habitats (Kadlec and Knight, 1995).

33.7.10.2.2 Civil Engineering

The shrink/swell nature of Vertisols severely limits civil engineering applications. Vertisols must be stabilized for construction of buildings, roads, pipelines, and utility corridors. For example, several major cities in Texas (Dallas, Houston, San Antonio, and Corpus Christi) have been built on Vertisols. The swell/shrink properties of Vertisols make effective construction site stabilization very difficult. The most economic choice may be to select stable soil (not Vertisols) for construction sites. If construction on a Vertisol is necessary, on-site investigation is generally required. Morphological properties of these soils often indicate movement at depths between 2 and 4 m due to natural moisture variability (Coulombe et al., 2000). These depths of movement suggest that soil management is the best way to minimize damage to structures on Vertisols and other expansive soils. Homeowners can maintain moist soils around the

foundations of their dwellings that are built on steel reinforced concrete slabs to minimize movement. Application of gypsum to reduce ESP minimizes excessive swelling of smectites.

Prior to construction of roads, streets, and many structures that are to be built on Vertisols, lime [Ca(OH)$_2$] stabilization of the soil is required to a depth of about 0.3 m or less (Eades and Grim, 1960; National Lime Association, 1991). Although this is beneficial, it obviously is only a partial treatment and complete stabilization would be extremely expensive. Larger multistory buildings sited on vertic soils and deep smectitic clays typically are supported by concrete piers with large bell-shaped feet at about 4 m depth to avoid contact with expansive soil.

Many other commercial methods to stabilize Vertisols are being promoted, some of which may be as successful as lime stabilization. One such treatment with a sulfonated naphthalene was tested under laboratory conditions on three Vertisols with some success (Marquart, 1995), but the results were inconsistent, depending on soil conditions and level of treatment.

It is imperative for construction workers to seriously consider the use of shoring materials and other safety precautions when a Vertisol is excavated. In Texas, from 1980 to 1985, 50 construction workers were killed due to destabilization of Vertisols that occurred during excavation (USDA-SCS, 1986).

33.7.11 Geological Studies of Lithified Paleosols Interpreted as Vertisols

33.7.11.1 Introduction

Vertisol-like paleosols here and elsewhere (hereafter referred to as "paleovertisols") are clay-rich paleosols that show abundant evidence for shrink–swell processes including slickensides, cracks, and strongly developed sepic–plasmic microfabrics. Vertisols are one of the few soil orders for which *Soil Taxonomy* can be easily applied to corresponding paleosols in the geological record (Mack et al., 1993). Paleovertisols have provided a wealth of information on paleoenvironment conditions, including Paleozoic (540 to 225 million years before present) levels of atmospheric CO$_2$ and changes in soil morphology accompanying the evolution and diversification of terrestrial land plants (Mora et al., 1996; Mora and Driese, 1999; Driese and Mora, 2001; Driese et al., 2005; Driese, 2009). Much of the interest in paleosols is driven by their potential to serve as climatic proxies in ancient environments.

Vertisols are characterized by macro- and micromorphologic characteristics formed in response to shrink–swell phenomena associated with either seasonal precipitation or seasonal soil moisture deficits. Many of these features preserve well in the ancient rock record in Paleovertisols and can be easily recognized in the field (in outcrop exposures and in cores) and in thin section; thus, Paleovertisols are increasingly reported in the geologic record, ranging in age from the Proterozoic (Rye and Holland, 2000; Driese, 2004) to the Cenozoic. Paleovertisols formed over a wide range of paleolatitudes, ranging from equatorial–low latitude (Appalachian basin; references cited below) to as high as 78° (Triassic of Antarctica; Retallack and Alonso-Zarza, 1998). Virtually every Paleozoic red bed formation in

the Appalachian Basin stratigraphic succession has common occurrences of Paleovertisols or vertic intergrades of other soil orders (Mora and Driese, 1999; Driese et al., 2000a; Driese and Mora, 2001; Stiles et al., 2001). The wide spatial and temporal distribution of Paleovertisols reflects the potential for their formation under wide ranges of moisture regimes (from semiarid to humid); the only strict climatic requirement is that the moisture is seasonally distributed. The widespread distribution also reflects the predominantly physical controls on Vertisol formation; these soils are not limited to specific environments or ecosystems. Retallack (1994) compiled a nonlinear relationship that predicts annual rainfall based upon the depth from the soil surface to pedogenic carbonate horizons. This relationship, based on measurements in carbonate-bearing soils representing a variety of soil orders, was better constrained specific for Vertisols by Nordt et al. (2006). Stable carbon and oxygen isotope analysis of pedogenic carbonate in Vertisols helps to elucidate the soil ecosystem (dominance of C$_3$ vs. C$_4$ flora) and changes in soil water compositions that may indicate climate change (Kovda et al., 2003, 2006). Similar information may be preserved in the isotopic compositions of Paleosols, as well as constraints on paleoatmospheric pCO$_2$ using Cerling's (1991) carbon isotope paleobarometer (Ekart et al., 1999).

33.7.11.2 Distribution of Fossil Vertisols in Geologic Record

Modern Vertisols today only comprise about 2% of world soils, far less abundant than most other soil orders recognized in USDA *Soil Taxonomy*, yet they appear to comprise the majority of paleosols preserved in the geologic record. Possible hypotheses that might explain this apparent overrepresentation of Paleovertisols in the geological record include the following:

1. There a strong recognitional bias for Paleovertisols in outcrop exposures and in cores because of ease of identification (discussed previously).
2. There are significant preservational processes biased for Vertisols. Because Vertisols are known to form very rapidly (within tens to hundreds of years, in some cases) and mostly in low-lying floodplains and lacustrine floodbasins, not much time is necessary for subaerial exposure and pedogenesis, and the resultant formation of a paleosol with high preservation potential. In addition, Vertisols can form over wide ranges of latitudes (e.g., from North Dakota to south Texas in the United States), and under wide ranges of moisture regimes. As such, they may have been more widely distributed in the geologic past than they are now. Because the physical processes of clay shrink–swell dominate soil-forming processes, plants may be unnecessary in Vertisol genesis (Mora and Driese, 1999). A wider temporal range (i.e., pre-Silurian) is therefore possible. This contrasts for example, with the distribution of soils with mollic epipedons (mostly Mollisols), the first appearance of which in the Tertiary is related to the appearance of dryland grasses (Retallack, 1997).

TABLE 33.35 Diagenetic Alteration of Paleovertisols (High Clay-Content Paleosols with Extensive Shrink–Swell Features Such as Slickensides) Compared with a Surface Soil Analog (Houston Black Series, TX)

Name (Geologic Age)	Burial Depth (km)	Burial Temperature (°C)	Clay Mineral Assemblage	wt% K_2O
Houston Black (modern)	Surface	22° Mean annual temperature	Na–smectite	1.29
Pennington (325 Ma)	2–3	60–90	Illite (+ kaolinite + chlorite)	4.61
Hekpoort (2.25 Ga)	12–15	350	Sericite–muscovite–chlorite	9.50

Ma, millions of years; Ga, billions of years. Note potassium enrichment occurring over time and with increasing burial depths and temperatures.

33.7.11.3 Paleoclimate Reconstructions Based on Fossil Vertisols

Paleoclimate reconstructions based on fossil Vertisols primarily emphasize estimation of mean annual precipitation (MAP) using a variety of proxy measures, including (1) depth to pedogenic carbonate (Bk) horizon (Caudill et al., 1996; Nordt et al., 2006); (2) Fe content of pedogenic Fe–Mn nodules and concretions (Stiles et al., 2001); (3) chemical indices of weathering used to estimate paleoprecipitation based on bulk geochemistry (e.g., Chemical Index of Alteration minus Potash or CIA − K, Sheldon et al., 2002 [note: CIA − K = molar ratio of $Al_2O_3/(Al_2O_3 + Na_2O + CaO) \times 100$, and the linear regression has an $r^2 = 0.73$], but a new paleoprecipitation proxy specific for Paleovertisols termed CALMAG has been developed where CALMAG = molar ratio of $Al_2O_3/(Al_2O_3 + CaO + MgO) \times 100$, and the linear regression obtained has an $r^2 = 0.90$; Nordt and Driese, 2010a); (4) total element mass-flux and mass-balance calculations (Driese et al., 2000b; Stiles et al., 2003); and (5) transfer functions for reconstructing colloidal properties of Paleovertisols from bulk geochemistry Nordt and Driese (2010b). Paleolandscape reconstructions in which topography or hydrology is important variable (interpretation of paleocatenas) are commonly conducted at both local and more regional scales. Reconstructions of Phanerozoic pCO_2 employ the CO_2-carbonate paleobarometer of Cerling (1991) to interpret Paleozoic (Mora et al., 1996; Mora and Driese, 1999) and Mesozoic paleoatmospheres from fossil Vertisols (Nordt et al., 2002, 2003). This technique utilizes the $\delta^{13}C$ values measured from pedogenic carbonates, measurements of $\delta^{13}C$ values of paleosol organic matter (or an estimate thereof based on marine proxy records), and assumptions of soil productivity (soil-CO_2 production rates) to estimate paleoatmospheric pCO_2. These results are in good agreement with pCO_2 estimates based on long-term mass-balance carbon models (Berner, 2006). Other research directions include systematic studies of root diameter, depth, and density in Paleosols using root traces, and relating these changes to development of soil morphology (Driese and Mora, 2001), widespread deposition of black shales, and carbon sequestration.

Problems in interpreting paleoclimates from pre-Quaternary fossil Vertisols include extensive burial diagenetic alteration and some compaction (Sheldon and Retallack, 2001). Commonly cited diagenetic alteration processes include physical compaction and consequent modifications of original soil thickness and morphology, oxidation of soil organic matter, burial gleization (Fe loss, largely through microbial reduction), color modifications (intensification) related to dehydration and recrystallization of hydrous mineral phases (such as FeOOH), recrystallization of soil smectites to illites (or even to metamorphic mineral assemblages; Table 33.35), and exchange of oxygen isotopes between burial fluids and pedogenic carbonates and clays (Mora et al., 1998; Mora and Driese, 1999). Evolutionary changes in terrestrial plant and animal communities over time also create difficulties in paleosol interpretations because of attendant changes in morphological features such as root traces, which are (1) not present in Ordovician paleosols; (2) rhizomatous and fine in Silurian paleosols; and (3) larger, deeper, and more "modern" in Devonian and post-Devonian paleosols (Driese et al., 2000a, 2000b; Driese and Mora, 2001).

33.8 Mollisols

P.A. McDaniel

R.G. Darmody

J.C. Bell

D.G. McGahan

33.8.1 Introduction

Mollisols are generally characterized as soils with thick, dark surface horizons (mollic epipedons) resulting from organic C incorporation. The terms mollic and Mollisol are derived from the Latin *mollis*, that is, soft. While the soil taxon, Mollisols, is defined by an exact set of soil property criteria, these criteria arose from conceptual ideas and empirical observations of soil landscapes with thick, dark, and often fertile surface horizons. Mollisols can form under multiple environmental conditions that facilitate accumulation of organic C in the upper soil profile. Although Mollisols correspond to the Chernozem soils of the Russian and older U.S. classification systems, the Mollisol soil order includes soils that are beyond the central concept of Chernozems (Fanning and Fanning, 1989).

Mollisols are among the most important soils for food and fiber production due to relatively high levels of native fertility coupled with climatic conditions conducive to plant growth. For this reason, the characteristics of Mollisols have been studied extensively, with early efforts focusing on the Chernozems of the Russian Steppes. During the late nineteenth century, droughts and crop failures afflicted the Russian Chernozem region resulting in widespread famine. In an effort to determine if the droughts could be prevented or moderated, Dokuchaev (1883) initiated an extensive study of the climate, soils, vegetation, and topography of the Chernozem Steppes. Based on the physical evidence that he and his colleagues collected, Dokuchaev theorized that the Chernozems of the Russian Steppes formed under specific conditions of climate, vegetation, and topography. These ideas contradicted the in vogue theories that Chernozems originated under either aquatic or marsh conditions. Dokuchaev's classic studies not only provided insight into the potential processes responsible for the formation of Chernozems, and subsequently Mollisols, but also articulated a conceptual framework for soil genesis that is still one of the foundations of modern pedology.

33.8.2 Geography and General Characteristics

33.8.2.1 Geographic Distribution

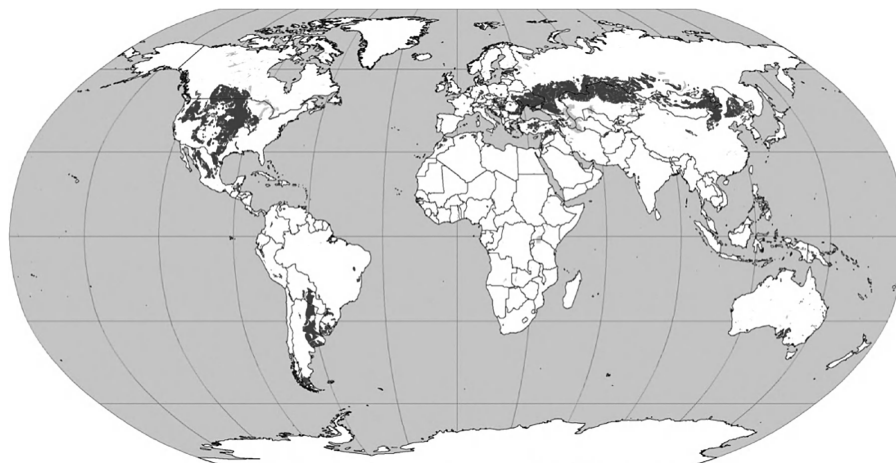
Extensive areas of Mollisols are distributed throughout the mid-latitudes of the world, predominantly on subhumid steppes and prairies (Figure 33.45). Mollisols occur under a wide range of climatic conditions including xeric, ustic, udic, and aquic soil moisture regimes and cryic, frigid, mesic, thermic, and hyperthermic soil temperature regimes. Spatially, Mollisols are the 8th (of 12) most common soil order and are estimated to cover


FIGURE 33.45 Global distribution of Mollisols. (Courtesy of USDA-NRCS, Soil Survey Division, World Soil Resources, Washington, DC, 1998.)

TABLE 33.36   Estimated Occurrence of Mollisol Suborders Worldwide by General Climatic Condition

Climatic Conditions	Major Geographic Locations	Mollisol Suborder	Approximate Land Area (km²)
Semiarid	Great Plains of United States and Canada, Southern Russia, Pampas Region of Argentina, Yucatan Peninsula of Mexico	Ustolls	5,244,636
Humid	Black Sea Region of Russia, North-Central United States, Western Europe	Udolls and Rendolls	1,526,878
Cold	Mountainous regions of the Western United States and Canada, higher latitudes across North America, Kazakhstan, Ukraine, and Russia	Gelolls and Cryolls	1,163,797
Mediterranean	Turkey, Argentina, Palouse Region of United States, California	Xerolls	924,394
Seasonally saturated	Red River Valley of North, riparian zones, Gulf coastal plain, glaciated regions of the United States	Aquolls and Albolls	145,728

9,005,433 km² or approximately 7% of the ice-free land area on Earth (Table 33.1). The distribution of Mollisol suborders can be distinguished by differences in climate, with the exception of wet Mollisols (Aquolls and Albolls), which typically occur in localized areas subject to saturated and reduced soil conditions (Table 33.36). The distribution of Mollisol suborders in the United States is shown in Figure 33.46. The close relationship of prairie ecosystems and Mollisols is apparent in the U.S. distribution where Mollisols are more common in the Western United States, west of the forested eastern half of the country. Noticeably, the "Prairie Peninsula" shows up in Figure 33.46 as the eastern expansion of Mollisols into Illinois and Indiana (Geis and Boggess, 1968).

33.8.2.2 General Characteristics of Mollisols

The general concept of Mollisols is that of dark colored soils of semiarid to subhumid grassland ecosystems. The dark color reflects soil organic matter (SOM) enrichment in the upper portion of the profile (Figure 33.47). The formation of dark surface horizons is termed melanization, which is actually a combination of several processes involving the addition of organic matter to the soil in the form of plant residues and its subsequent transformation into humus (Buol et al., 2003). Distinguishing features of Mollisols include the presence of a mollic epipedon and high base status (Soil Survey Staff, 2010). A mollic surface layer by itself is not diagnostic for Mollisols, as it can be a feature of soils belonging to other orders. Mollisols are differentiated in these cases by the presence of high base status (>50% base saturation) horizons that underlie the mollic epipedon, or by the lack of features associated with high shrink/swell clays, typical in Vertisols (Graham and Southard, 1983). A wide variety of subsurface horizons can occur beneath the mollic epipedon of Mollisols, including albic, cambic, argillic, calcic, petrocalcic, natric, duripans, and gleyed horizons. However, fragipans are unknown in Mollisols (Franzmeier et al., 1989). The nature of
FIGURE 33.47 Soil profile of a Mollisol showing thick, dark mollic epipedon. The mollic epipedon extends to a depth of almost 60 cm; scale is in decimeters.

any diagnostic horizon is usually expressed at the great group level in classification with the exception of Albolls (albic) and Aquolls (gleyed).

A mollic epipedon is defined in *Soil Taxonomy* by several quantitative criteria including horizon thickness, organic C content, color, consistence, structure, and base status (Soil Survey Staff, 1999, 2010). Although a mollic epipedon must contain at least 1% SOM (0.6% organic C) on a weight basis, many Mollisols have higher SOM contents. A mollic epipedon must generally be a minimum of 18 cm thick for shallow and 25 cm thick for deep soils. Soils, which are very shallow, require only a 10 cm thick mollic epipedon (Soil Survey Staff, 2010). Munsell color requirements include a value (a measure of lightness/darkness) that is 3 or less for a moist sample and 5 or less for a dry sample. In both cases, the chroma (intensity or purity of color) is 3 or less. Thus, the colors of a mollic epipedon range from black or very dark brown when moist and are somewhat lighter (higher value) when dry. The color criteria were established as a field criterion to separate high organic matter soils formed under grasslands from their lower organic matter counterparts under forest. Mollic epipedons often have well-developed granular structure that is quite friable. By definition, a mollic epipedon cannot be both hard and massive when dry. A minimum of 50% base saturation is required for a mollic epipedon indicating a dominance of basic cations, primarily Ca and Mg, occupying cation exchange sites.

The high base status of Mollisols generally translates into a high level of native fertility. Both calcium and Mg, typically the dominant exchangeable cations, are required in fairly large quantities for plant growth. The pH values for Mollisols may be quite variable ranging from strongly acid (5.1–5.5) to strongly alkaline (8.5–9.0). However, many Mollisols have pH values somewhere in the middle of this range and are generally considered to be favorable for plant growth without widespread use of liming agents. Their high native fertility is one of the main reasons for their extensive use in agriculture throughout the world.

Mollisols generally have not undergone intensive weathering, and therefore, their mineralogy is often dominated by minerals inherited from their parent materials. Many Mollisols have formed in recently deposited parent materials such as glacial till and loess, which has not allowed sufficient time for significant mineral weathering to occur. Mineral weathering is also limited by the cooler temperatures and/or lack of moisture that are associated with many Mollisols. Clay mineralogy of Mollisols is typically dominated by 2:1 layer silicates, including clay-sized mica (illite), smectite, and vermiculite (Allen and Fanning, 1983). Generally, kaolinite, a 1:1 layer silicate, is commonly found in Mollisols although in small quantities (Allen and Hajek, 1989). However, soils dominated by kaolinite, such as the Ewa soil series from Hawaii (a fine, kaolinitic, isohyperthermic Aridic Haplustoll), are sometimes found (USDA-NRCS, 2009).

Many of the physical characteristics of Mollisols are influenced by SOM and the associated biological processes. The relatively high SOM content of Mollisols is conducive to the formation of water-stable aggregates, which typically have crumb or granular structure, and is formed and maintained by the interaction of plant roots, microbial structures, and biological molecules (Tate, 1992). This type of stable structure is important for good water infiltration and reduced susceptibility of soils to erosion. Organic matter plays a considerable role in enhancing the water-holding capacity of Mollisols, as it can hold up to 20 times its weight of water (Stevenson, 1994). The dark colors associated with Mollisols are attributable to the humic fractions of SOM, which are black and mask the lighter colors associated with fulvic fractions (Schultze et al., 1993).

33.8.3 Classification

Soils classified as Mollisols in *Soil Taxonomy* can be divided into 8 suborders and 37 great groups. While all these soils have a mollic epipedon, they are separated into the various suborders largely on the basis of their climatic regimes. Mollisols include soils that were formerly classified as Chernozems, Brunizems, Chestnut, and Rendzina soils and some soils formerly classified as Brown, Brown Forest, Humic Gley, and Planosols (Fenton, 1983). Table 33.37 lists the suborders, great groups, and subgroups in the Mollisol order. Tables 33.38 and 33.39 list the estimated areal extent of the Mollisol suborders and great groups in the NRCS database for the United States.

33.8.3.1 Albolls

Albolls are the sixth most commonly mapped Mollisol suborder (Table 33.38). They have a well-developed, light-colored horizon (albic) and a fluctuating water table. The albic horizon forms as pigmenting agents such as SOM, clays, and Fe oxides are

removed from mineral grains (primarily quartz) exposing their light color. In Albolls, the albic horizon typically occurs just below the mollic surface layer and directly above a less permeable horizon of clay accumulation, an argillic horizon. Albolls often have a water table at or near the surface for several months during the winter and spring. In the United States, Albolls are most extensive in loess deposits of the Midwest (Figure 33.46).

33.8.3.2 Aquolls

Aquolls are the sixth most commonly mapped Mollisol suborder (Table 33.38). They are the wettest Mollisols and are characterized by the presence of redoximorphic features below a thick and very dark brown or black epipedon. Depending on the duration of wet conditions and Fe reduction, expression of Fe-depleted zones can range from entire horizons with predominantly dull gray colors to horizons that have a strongly contrasting mottled gray color pattern. They typically occupy the lower lying areas of the landscape where water accumulates and a high water table exists. The most extensive areas of Aquolls in the United States occur in the Red River Valley of the North, along floodplains and terraces of major rivers in the central part, and along the Gulf coastal plain (Figure 33.46). Most uses of Aquolls, whether urban or agricultural, are limited by wetness. Many Aquolls are suitable for agriculture if artificially drained. Aquolls typically have black surface horizons underlain by gray colors indicating reduction and/or depletion of Fe (Table 33.40). Organic C accumulates in the surface horizon due to reduced rates of organic matter decomposition resulting from seasonal anaerobic conditions. The presence or absence of carbonates in Aquoll profiles is quite variable and can be used as an indicator of wetland hydrology. Carbonates tend to be removed from recharge wetlands by leaching, whereas discharge wetlands are enriched often to the soil surface. Depressional basins in subhumid climates often have recharge hydrology resulting in leaching of carbonates and formation of argillic horizons (Mausbach and Richardson, 1994).

33.8.3.3 Rendolls

Rendolls form in highly calcareous parent materials of humid or cold regions, often under forest vegetation. These soils typically consist of a mollic surface layer overlying mineral material that contains >40% $CaCO_3$ by weight (Soil Survey Staff, 2010). Rendolls are associated with parent materials such as chalk, limestone, highly calcareous glacial till, and shell deposits. These soils are not extensive in the United States where only a few soils, <1% of all Mollisols, have been recognized (Table 33.38). However, Rendolls are extensive in Western Europe (Smith, 1986).

33.8.3.4 Gelolls

Recent changes in *Soil Taxonomy* have made the presence of permafrost in the soil profile the first criterion for classification at the order level (Soil Survey Staff, 2010). Soils with permafrost within 100 cm of the surface, or within 200 cm with gelic materials, classify as Gelisols (see Section 33.6). Mollisols with a gelic soil temperature regime, that is, mean annual soil temperature (MAST) ≤0°C, are classified as Gelolls; these were formerly classified as

TABLE 33.40   Selected Morphological, Physical, and Chemical Properties of an Aquoll from Southern Minnesota

Horizon	Depth (cm)	Texture	Moist Color	Clay (%)	pH	Organic C (%)	Cation Exchange Capacity (cmol$_c$ kg^{-1})	CaCO$_3$ (%)

Cg2	105–125	Loam	Gray	25.3	7.6	0.2	18.8	12

Location: Waseca County, Minnesota; mean annual air temperature: 6.2°C; mean annual precipitation: 836 mm; vegetation: Reed canary grass (*Phalaris arundinacea* L.), Cattails (*Typha* sp.); parent material: Wisconsinan-age glacial till; landscape position: depression, 0%–1% slope; classification: fine-loamy, mixed, mesic, Typic Endoaquoll.

Pergelic Cryoborolls (see the discussion on the fate of Borolls in Section 33.8.3.5). Gelolls are required to have a mean summer soil temperature (MSST) of ≤8°C, if no O horizon, or ≤5°C, if an O horizon is present; otherwise, they classify as Cryolls. Gelolls are rare and essentially not useful for agriculture. They are exclusively found at high elevations and latitudes. There is only one recognized soil series in the Geloll suborder; it is the Kanauguk series, a loamy-skeletal, mixed, mesic, superactive, subgelic Lithic Haplogeloll, found in Alaska. Consequently, only 30 ac (~0.1 km²) of Gelolls are represented in the NRCS database (Tables 33.38 and 33.39).

33.8.3.5 Cryolls

Cryolls occur in cold climates having a mean annual soil temperature <8°C with cool summers, but do not have permafrost. Cryolls are a replacement for the Cryoboroll great group of Borolls that was discontinued when the Boroll suborder was removed from *Soil Taxonomy* in 1998 (Soil Survey Staff, 1998). The fate of other Great Groups of Borolls is not as clear because not all soils that were classified formerly as Borolls have been reclassified and entered into the NRCS database. However, in addition to the placement of Cryoborolls (except Pergelic Cryoborolls, which are now Gelolls) into Cryolls, the convention for placement of former Borolls into the revised taxonomy is somewhat complicated. Borolls were defined as having a frigid, cryic, or pergelic temperature regime. As a result Borolls that had a pergelic regime and permafrost are now Gelisols, and those with a pergelic temperature regime, but no permafrost, are now Gelolls as discussed in Section 33.8.3.4. Those with a cryic temperature regime would have gone to Cryolls as discussed above. Those with a frigid temperature regime would have gone to Udolls and Ustolls but not to Xerolls because Xerolls preceded Borolls in the seventh edition key to *Soil Taxonomy* (Soil Survey Staff, 1975).

Cryolls are relatively rare, ~5% of mapped Mollisols in the United States (Table 33.38) and generally are associated with a short growing season that limits their use for agricultural production. They can, however, be productive for some cold-tolerant crops such as potatoes and for small grains and hay production where practicable. Large quantities of organic C are typically associated with such soils giving a strong black color to the mollic epipedon. Cryolls are generally found at higher latitudes or elevations. In fact, the most northerly Mollisol described in the literature is a loamy-skeletal, micaceous, isofrigid, Typic Haplocryoll found under tundra vegetation in Arctic Sweden at 68°23.32′N, 18°20.40′E, and at 775 m elevation on a 78% slope (Darmody et al., 2000). Its mean annual soil temperature of 1.2°C barely keeps it out of the Gelolls.

33.8.3.6 Xerolls

Xerolls form in areas that receive the majority of precipitation during the winter and spring months when temperatures are cool (Mediterranean climates). Little precipitation is received during the growing season and, as a result, Xerolls frequently become dry at some point during the summer. This type of moisture regime is very effective for leaching CaCO$_3$ and other soil constituents in higher precipitation zones. Conversely, Xerolls of the drier areas are subject to long periods of soil moisture deficits during the growing season. In the United States, Xerolls comprise ~15% of the land area occupied by Mollisols and are restricted to the western states (Table 33.38, Figure 33.46). An example of a Xeroll profile from the Palouse region of northern Idaho is shown in Figure 33.48, with selected data in Table 33.41. Important features of this soil include the lack of CaCO$_3$ in the profile, acidic conditions, and dense subsoil horizons (bulk density >1.7 g cm^{-3} at 94–152+ cm). Effective leaching by winter precipitation is responsible for the lack of CaCO$_3$ and the low pH. The dense subsoil horizons restrict downward water movement and result in the formation of perched water tables during the winter and spring months. Xerolls are used primarily for production of wheat, hay, and some timber.

33.8.3.7 Ustolls

Ustolls occur in subhumid or semiarid climates receiving significant amounts of spring and summer rain (350–900 mm annual precipitation), which is characteristic of the ustic soil moisture regime (Figure 33.46). As a result, the potential productivity of these soils for agriculture varies considerably. In the higher rainfall areas, drought-sensitive crops, such as corn and soybeans, can be produced, while in the drier regions, summer fallow, which allows recharge of soil moisture in a fallowed field (typically every other year), is often necessary for crop production (Soil Survey Staff, 1999). Ustolls are extensive throughout the central Great Plains and are the dominant suborder (~45% of the total Mollisol area) in the United States (Table 33.38). Data from
FIGURE 33.48 Soil profile of a Xeroll from northern Idaho. Accompanying data are in Table 33.41; scale is in decimeters.

a representative Argiustoll profile from Montana are presented in Table 33.42. Limited leaching in this profile has resulted in the removal of CaCO$_3$ from the upper 61 cm and the development of acid pH values near the surface. Base saturation increases with depth and is generally ~100% in lower horizons where CaCO$_3$ has accumulated. This particular pedon is from a frigid soil climate, and in this region, these soils are mainly used for winter wheat and hay production. However, often it is the dryness of Ustolls that limits agricultural productivity.

33.8.3.8 Udolls

Udolls occur in humid regions having typically formed in late Pleistocene or Holocene deposits under tall grass prairie

(Figure 33.46). They are the second most commonly mapped suborder, accounting for about 21% of the Mollisols in the NRCS database (Table 33.38). Udolls are characterized by having moderate precipitation, well-distributed throughout the year (Soil Survey Staff, 1999). Because extended soil moisture deficits are not experienced, and their high natural soil fertility, most Udolls have been placed into agricultural production. Udolls are extensive in the Midwestern United States and comprise one of the most productive grain-producing regions of the world (Soil Survey Staff, 1999). The famous Morrow Plots on the University of Illinois campus, where corn has grown continuously for well over 100 years, are developed in Udolls (Darmody and Peck, 1996). Corn and soybeans, which are among the principal crops produced on Udolls, are generally not produced or produced with higher risks, on other Mollisols because of climatic limitations. Data for a Udoll from Iowa are presented in Table 33.43. Although the parent material is calcareous loess, the relatively high annual precipitation has completely removed CaCO$_3$ from the upper 175 cm. Calcium is still the dominant soil cation and, with Mg, occupies most of the CEC.

33.8.4 Pedogenic Processes

Soils classified as Mollisols develop under a variety of environmental conditions through several distinct genetic pathways. Soil genesis typically occurs over time frames where environmental conditions, and hence the theoretical equilibrium state, are variable. The morphological imprints left by grassland vegetation are ephemeral in pedogenic time frames, and hence, are probably indicative of the soil climate over the past few hundreds to thousands of years. The genesis of Mollisols will be discussed from two different perspectives (factors and processes of soil formation) in an attempt to elucidate the development of these unique soils.

33.8.4.1 Factors of Soil Formation

The factor approach applied by Jenny (1941, 1980) to the soil-forming factor model is predicated on the hypothesis that soil properties result from the interaction of at least five site and flux factors. This model proposes that soil bodies result from

the action of climate, organisms, and relief acting upon parent material over time and provides a useful conceptual framework by which soil differences can be attributed to state or site factors.

33.8.4.1.1 Organisms

To a large degree, Mollisols are distinguished from other soils on the basis of organisms, or more specifically, the overriding effects of grassland vegetation. The reason why grassland vegetation imparts distinctive soil morphologies is discussed later. While some Mollisols have developed under consistent vegetative conditions, abundant evidence suggests that many were forested during glacial and postglacial periods (Walker, 1966; Ruhe, 1970; Wright, 1970). Similar evidence also suggests that the climate has changed sufficiently during the Holocene to allow fluctuations between forest and prairie vegetation, especially along humid to subhumid ecotones (Walker, 1966; Geis and Boggess, 1968). Most soils classified as Mollisols (with the possible exception of some Rendolls, Aquolls, and Albolls) have

probably had grassland vegetation at some time during their development. Because soil characteristics reflect the integration of the soil-forming factors over long time periods (centuries to millennia), the contemporary environment may or may not accurately reflect the conditions under which a soil has developed. Mollisols are common in transitional areas between humid and subhumid environments such as the north central United States. Changes in climate during the Holocene have probably resulted in the formation and subsequent degradation of Mollisols as forest encroached on areas that were previously prairies (Fenton, 1983).

The mixing and incorporation of organic matter within the mollic epipedon have also been attributed to soil faunal activity. Of particular importance are burrowing organisms, such as gophers, prairie dogs, worms, and ants (Thorp, 1948; Munn, 1993). The net effect of burrowing activities is to move organic matter lower in the soil profile and to mix soil materials, resulting in a rather homogeneous epipedon.

33.8.4.1.2 Climate

As previously suggested, climate is also a key factor in the formation of Mollisols, primarily through its effect on vegetation. Grassland ecosystems are associated with broad ranges in mean annual precipitation and temperature. Consequently, Mollisols occur under a wide range of soil temperature and moisture regimes. In the United Sates, these soils are found from as far south as Texas to the Canadian border and into Alaska. Mollisols are most common in the zone between the arid deserts of the Western states and the forests of the Midwestern states, a range of approximately 300 mm to more than 900 mm in annual precipitation (Figure 33.46).

The effects of climate on Mollisol formation can be demonstrated by comparing soil morphology along climatic gradients. Munn et al. (1978) examined a warm/dry-to-cool/moist sequence of grassland soils in Montana. They observed an increase in annual aboveground biomass production with increasing precipitation and decreasing temperature (Figure 33.49). Similarly, SOM content, which increased as well, is expressed by increasing thickness of the mollic epipedon. This suggests that the dark, organically enriched mollic epipedon provides a record of the balance between annual site production and microbial decomposition. As production increases with increasing precipitation, decreasing temperature favors the accumulation of SOM by decreasing microbial decomposition rates. Leaching of $CaCO_3$ in the soils was greater with increasing annual precipitation, indicating that depth to carbonate serves as an indicator of rainfall within a geographic region.

33.8.4.1.3 Relief

The local topography or hillslope position affects hydrologic processes, especially erosion and sedimentation and the timing, duration, and depth of seasonal soil saturation. Many glacial till landscapes of the eastern portion of the central United States
FIGURE 33.50 Glacial till landscape in central Indiana (the easternmost portion of the "prairie peninsula") showing patterns of Alfisols (light tones) and Mollisols (dark tones). Wet Mollisols (Aquolls) occupy lower lying, wetter portions of the landscape. Alfisols are found in the higher, better drained positions. (Photo used with permission of the Soil Science Society of America.)

contain both Mollisols and Alfisols, the "Prairie Peninsula" (Geis and Boggess, 1968). Aquolls and Albolls occur in the wetter, lower lying portions of the landscape (darker soil surface; Figure 33.50). Conversely, Alfisols occupy the adjacent higher positions having better drainage (Allen and Fanning, 1983).

Richardson et al. (1992) proposed a framework to view wetland hydrology based on differences in how water flows through depressional basins (recharge, flowthrough, or discharge). Differences in basin hydrology result in distinctive differences in soil morphology along hillslopes (Thompson and Bell, 1996; Bell and Richardson, 1997). Examination of a toposequence of Mollisols from south central Minnesota illustrates typical catena relationships (Figure 33.51). Along this hillslope continuum, the following changes occur from upper to lower landscape positions: (1) increased darkness (organic C) and thickness of the surface

FIGURE 33.49 Generalized relationship between aboveground productivity in rangelands in Western Montana, depth to $CaCO_3$, and thickness of mollic epipedon. (Adapted from Munn, L.C., G.A. Nielsen, and W.F. Mueggler. 1978. Relationships of soils to mountain and foothill range habitat types and production in western Montana. Soil Sci. Soc. Am. J. 42:135–139. FIGURE 33.53 Depth distributions of soil organic carbon at four hillslope positions in glacial till near Waseca, Minnesota.

horizon, (2) decreased depth to redoximorphic features, and (3) decreased chroma of the subsurface horizons. These morphological differences can often be traced back to differences in soil processes, such as erosion, deposition, and reduction that are affected by hydrology and the shape and position on the hillslope. Numerous studies have documented increased duration of saturation in lower landscape positions for similar landscapes (Khan and Fenton, 1994; Bell et al., 1995; Thompson and Bell, 1996). For the example from Waseca, Minnesota (Figure 33.52), higher carbonate concentrations between 45 and 90 cm at the toeslope are probably indicative of discharge hydrology and subsequent enrichment of the soil profile from carbonate laden groundwaters. The distribution of organic C with depth along the hillslope clearly indicates a trend of increasing organic C in the surface horizons from upper to lower hillslope positions (Figure 33.53). Organic C concentrations tend to converge at a depth of approximately 75 cm for all landscape positions where concentrations fall below 0.5%. These same spatial relationships cannot be assumed for all hillslopes as differences in soil stratigraphy, regional hydrology, and climate can cause different spatial patterns to develop.

33.8.4.1.4 Parent Material

Mollisols occur on a variety of substrate materials, but are most commonly associated with unconsolidated sediments from coastal, riverine, or glacial depositional environments, including loess (Soil Survey Staff, 1999). Loess is a common parent material of Mollisols in the Midwestern United States and in southern and central Russia. Duchaufour (1982) has suggested that the permeability and $CaCO_3$ content of loess is especially conducive to the formation of Mollisols. Many Mollisols have formed in calcareous parent materials resulting in appreciable quantities of $CaCO_3$ within the soil profile, particularly those Mollisols in
lower precipitation areas. Rendolls form exclusively in highly calcareous parent materials such as chalk, limestone, and shell deposits.

33.8.4.1.5 Time

Most Mollisols in the United States and Russia appear to be relatively young and have formed on late Pleistocene and Holocene deposits and surfaces (Soil Survey Staff, 1999). However, the recognition of Mollisols in intertropical areas may warrant reexamination of this concept. It has been shown that accumulation of SOM occurs relatively fast. Schafer et al. (1980) compared organic C levels in newly created mine soils with those of adjacent undisturbed grassland soils of eastern Montana and found that only 30 years was required for C to build up in the top 10 cm to the level in undisturbed soils. In Iowa, the rate of formation of a Udoll surface horizon was estimated at 0.08 cm year^{-1} (Buol et al., 2003). Foss et al. (1985) suggested that mollic epipedons developed in <900 years in the Red River Valley of the North in Minnesota and North Dakota. From these and other studies, it is clear that the formation of a mollic surface horizon can occur in relatively short time spans.

33.8.4.2 Genetic Pathways for Mollisol Formation (Soil Processes)

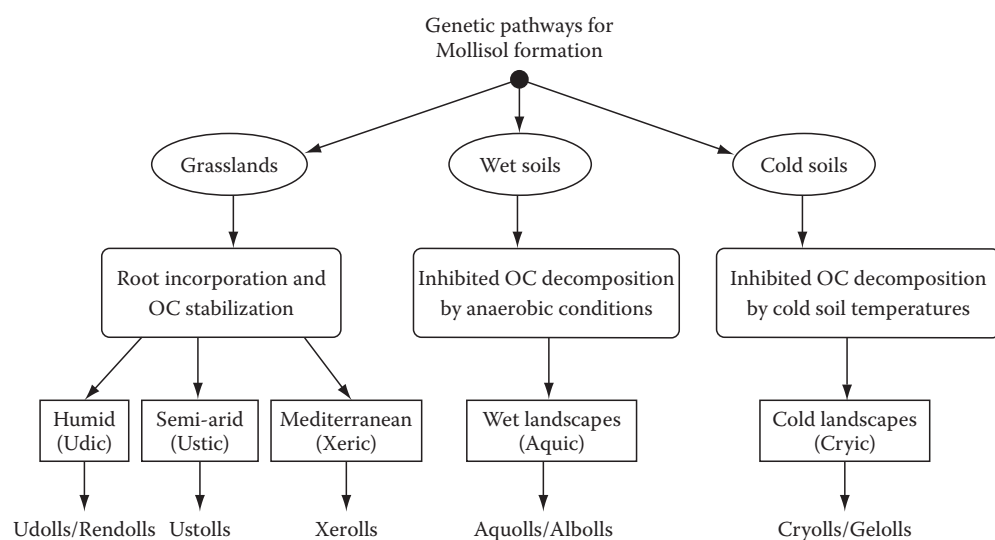
The accumulation of organic C in the upper soil profile is the salient morphological feature distinguishing Mollisols from other soil orders. The C content is high when the long-term rate of addition and retention exceeds that of decomposition. Rates of annual root production and decomposition in grasslands result in high rates of organic C turnover in the soil to depths often approaching 50–100 cm (Dahlman and Kucera, 1965; Dormaar and Sauerbeck, 1983). Thorp (1948) estimated that 113–409 kg ha^{-1} of raw OM (dry weight) were added annually for short grass and 136–500 kg ha^{-1} for tall grass prairies. Alternatively, soil organic C accumulates when rates of microbial decomposition are low due to either anaerobic (wet) conditions or cool


FIGURE 33.54 Theoretical pathways for Mollisol genesis.

soil temperatures (Jenny, 1930). Three primary pathways for Mollisol genesis based on the mode of organic C accumulation can be identified: (1) high rates of accumulation in grasslands, (2) low rates of decomposition under anaerobic (wet) conditions, and (3) low rates of decomposition in cold climates (Figure 33.54). These pathways are not necessarily mutually exclusive. For example, many wet soils may have also developed under grassland, but wet grassland soils frequently have higher organic C contents than drier soils in the same landscape (Figures 33.50 and 33.53).

33.8.4.2.1 Grassland Mollisols (Udolls, Ustolls, and Xerolls)

A comparison of the chemical composition and growth forms of forests and grasslands explains why soils under these covers have distinctive morphologies. In forests, organic C tends to accumulate on the soil surface from annual decomposition cycles of forest floor litter. Despite the fact that the forested soils (Alfisols) receive more annual precipitation, they contain less organic C throughout the mineral soil and lack the dark soil colors associated with Mollisols. Much of the organic matter associated with the forest soils is contained in litter layers lying on top of the mineral soil. Leachate from the decomposition of forest floor litter is often composed of carbonic, fulvic, and/or tannic acids facilitating translocation (eluviation) of soil materials deeper within the soil profile resulting in morphological features usually associated with Alfisols and Spodosols. These conditions and processes inhibit the accumulation and stabilization of organic C in the upper soil layers.

By contrast, photosynthesis and other metabolic processes in grassland vegetation quickly transport organic C to dense and fibrous root systems. Estimates indicate that grasslands have the highest annual additions of C to soil of any of the terrestrial ecosystems, including tropical forests (Bolin et al., 1979). Related research has demonstrated that the greatest biomass production in grassland ecosystems is below ground (Caldwell, 1975; Lauenroth and Whitman, 1977; Jenny, 1980). As such, Mollisols
FIGURE 33.55 Depth distribution of soil organic carbon in Mollisols and Alfisols of the Palouse region of Northern Idaho. The Mollisols have formed under Idaho fescue grassland with approximately 580 mm of annual precipitation; the Alfisols have formed under grand fir forest with approximately 830 mm of annual precipitation. (Data courtesy of the Soil Characterization Laboratory, University of Idaho, Moscow, ID.)

have distinctive organic matter profiles with depth that differ markedly from Alfisols, where most of the biomass is produced aboveground (Figure 33.55). The annual proliferation of roots and their subsequent decomposition is responsible for the deep accumulation of SOM leading to the formation of mollic epipedons whose thickness is largely determined by the depth and amount of grass roots (Hole and Nielsen, 1968; Cannon and Nielsen, 1984). Incorporation of organic C is also facilitated by the mixing of near-surface soil horizons by ants (Formicidae),

earthworms (*Lumbricus*), and other soil fauna (Curtis, 1959; Baxter and Hole, 1967). Schlesinger (1977, 1991) have estimated that temperate grassland soils have a mean organic matter content of 19.2 kg C m^{-2}, ranking them behind only soils of wetlands and tundra/alpine ecosystems on a global scale.

Grasses have another effect that differs from forest vegetation on soil genesis. Grasses are generally better base cyclers. That, in part, accounts for the higher fertility of Mollisols when compared with forest soils such as Alfisols. In addition, that difference also accounts for the absence of fragipans in Mollisols (Franzmeier et al., 1989).

Once added to the soil, organic materials undergo further decomposition by complex, microbially mediated processes that results in the formation of a relatively stable organic fraction. The large annual additions of C to Mollisols and subsequent cycling result in the formation of an active (bioavailable) as well as a very stable organic fraction. The humus contained in Mollisols appears to be more stable than that found in other soils (Stevenson, 1994), which is possibly related to the chemical composition of grasses and soil parent material. Grasses have a higher ratio of humic to fulvic acids (Glazovskaya, 1985). Novak and Smeck (1991) found higher concentrations of humic substances in the surface horizons of Mollisols compared with Alfisols in southwestern Ohio where these soils are adjacent in the same landscape. Minimal differences were found in fulvic acid content. The combination of humic substance in the presence of calcareous soil parent material results in the formation of Ca humates that are thought to bind silicate grains to organic C, which becomes stabilized (Evans and Russell, 1959; Stevenson, 1994). Formation of these complexes increases the resistance of SOM to physical disintegration, chemical extraction, and further biological change through microbial decomposition (Oades, 1989; Stevenson, 1994). Estimates as to the extent of organic matter–mineral associations in grassland soils vary. As much as 80% of the organic C in a mollic epipedon may be so closely associated with the mineral fraction that it cannot be separated by physical means (Greenland, 1965; McKeague et al., 1986). Researchers have been able to determine mean residence time (MRT) of organic fractions of Mollisols in several different environments. The MRT represents the average length of time that an organic fraction has been present in the soil. Oldest MRT values measured in soils are associated with Mollisols and Histosols (Oades, 1989). For example, MRT values between 1255 and 2973 years have been measured for Mollisols in Canada and the United States (Anderson and Paul, 1984; Hsieh, 1992).

The stabilization of organic C in mollic epipedons is also facilitated by soil clays. Organic C associated with fine clays is protected from further rapid decomposition lengthening the turnover time of otherwise labile humic substances from days to months, years, or even decades (Anderson and Paul, 1984). Anderson (1979) found that as much as 50% of the total humus in some grasslands is associated with clay. From these and other studies, it appears that texture is an important factor in determining the stable level of organic C in Mollisols as well as in other soils. Texture influences the water-holding capacity of a soil and the quantity of clays available to form
FIGURE 33.56 Relationship between clay and organic matter content in warm grassland soils of the southern United States. (Adapted from Nichols, J.D. 1984. Relation of organic carbon to soil properties and climate in the southern Great Plains. Soil Sci. Soc. Am. J. 48:1382–1384. With permission of the Soil Science Society of America.)

complexes with organic matter. Nichols (1984) observed a good correlation ($r = 0.86$) between soil organic C and clay content in 65 Mollisols and associated soils of Texas, Oklahoma, and New Mexico where mean annual temperatures exceed ~15°C (Figure 33.56). These data indicate that water-holding capacity and the protection afforded to humus through formation of mineral–organic complexes may control the equilibrium organic C contents in Mollisols of warmer regions. In contrast, clay content does not appear to exert such strong control of organic C contents in Mollisols of cooler regions. McDaniel and Munn (1985) found little correlation between SOM and clay in 137 Mollisols and associated soils in Montana and Wyoming having mean annual soil temperatures <8°C (Figure 33.57). Comparison of these data with those of Nichols (1984) suggests that it is temperature rather than moisture that becomes the determining factor in establishing an equilibrium SOM content. Furthermore, organic matter may be able to
FIGURE 33.57 Relationship between clay and organic matter content in cool grassland soils of the northern United States. (Adapted from McDaniel, P.A., and L.C. Munn. 1985. Effect of temperature on organic carbon–texture relationships in Mollisols and Aridisols. Soil Sci. Soc. Am. J. 49:1486–1489. With permission of the Soil Science Society of America.)

persist in cold soils without the stabilizing influence afforded by complexation with clays (McDaniel and Munn, 1985).

33.8.4.2.2 Wet Mollisols (Albolls and Aquolls)

An alternate genetic pathway for the development of Mollisols involves organic C accumulation under anaerobic soil conditions due to reduced rates of organic matter decomposition (Ponnamperuma, 1972; Gambrell and Patrick, 1978; Tate, 1980). These Mollisols have an aquic soil moisture regime and are classified as Aquolls or Albolls. The decomposition of organic matter is less efficient under anaerobic conditions, and a net accumulation of SOM will occur if rates of biomass production are sufficiently high. If this rate of organic matter accumulation is high enough, organic soils (Histosols) will develop. In many landscapes, Mollisols are found at the transition between organic and mineral soils.

In general, Aquolls have black (N 2/0) surface horizons with predominant gleyed or depleted horizons directly beneath the surface horizon (Table 33.40). Increases in the duration of soil saturation and anaerobic conditions are usually associated with higher soil organic C contents (Khan and Fenton, 1994; Bell et al., 1995). Topographically, organic C increases downslope as evidenced by the darker soil surfaces in lower landscape positions (Figure 33.51) associated with higher surface concentrations of organic C in depressional areas (Figure 33.53). Thompson and Bell (1996) found good agreement between a profile darkness index based on the thickness and darkness of the surface horizons and the duration of saturation for soil hydrosequences at several locations in the United States. They also found that the profile darkness index was highly correlated with soil organic C for the soils that were derived from glacial deposits.

Soil saturation, the development of anaerobic conditions and subsequent reduction of Fe(III) to Fe(II), causes the formation of distinctive color patterns (redoximorphic features) in the horizons beneath the mollic epipedon. Biochemical reduction results in the translocation of Fe compounds, which are the primary determinants of soil color in low organic matter horizons. The processes involved in the development of redoximorphic features are discussed in Chapter 15. If the soil water is stagnant, Fe(II), which has a distinctive bluish or greenish color, may be present, thus creating a reduced (or gleyed) soil matrix. More commonly, the soil water is moving, and Fe(III) coatings on mineral grains will be reduced and removed as Fe^{2+} ions, leaving the mineral grains and revealing the dull, gray color of the uncoated minerals, thus forming redoximorphic depletions. Under conditions of fluctuating water tables, Fe(II) may be reoxidized creating discrete concentrations of orange or reddish Fe(III) (Vepraskas and Sprecher, 1997). Bell and Richardson (1997) discuss specific soil process and morphologies associated with Aquolls and Albolls.

33.8.4.2.3 Cold Mollisols (Gelolls and Cryolls)

The formation of Mollisols under cold conditions (i.e., cryic or gelic soil temperature regimes) is somewhat analogous to the formation of wet Mollisols. Low soil temperatures (similar to lack of soil O_2) reduce microbial activity and facilitate organic matter

accumulation if the long-term rate of biomass production exceeds that of decomposition. Again, as previously covered, where permafrost is within 2 m of the soil surface, the soils are classified as Gelisols, and further classified as Histels if they are dominantly composed of organic soil materials (see Section 33.2). Where permafrost is lacking, or deeper than 2 m, and where rates of organic matter accumulation are high, the soils are dominated by organic matter and are in Cryo great groups of Histosols (Cryofibrists, Cryofolists, Cryohemists, and Cryosaprists). Cold Mollisols, which are classified as Cryolls or Gelolls, develop in areas where organic matter accumulation rates are somewhat lower than are necessary for organic soil materials to accumulate. Gelolls and Cryolls, along with their wet but warmer analogs, Aquolls and Albolls, often develop under grasslands, or tundra-like vegetation in the case of the cold Mollisols, but can develop under other types of vegetation where conditions are favorable.

33.8.4.3 Associated Pedogenic Processes

The following processes are also important in the formation of some Mollisols.

33.8.4.3.1 Carbonate Translocation

The dissolution of $CaCO_3$ and its subsequent precipitation as secondary carbonates lower in the soil profile is common in many calcareous parent materials where sufficient leaching takes place. Carbonates in layers of maximum accumulation are more finely divided than those associated with the parent material supporting secondary carbonate formation (Redmond and McClelland, 1959). Total precipitation is important in determining the depth at which $CaCO_3$ is deposited (Jenny, 1941). In many Xerolls, where precipitation is low but exceeds evapotranspiration especially in winter, $CaCO_3$ is readily mobilized and reprecipitated at depth. In the Palouse region of eastern Washington and northern Idaho, $CaCO_3$ has been removed from the upper 1.5 m of the profile in Xerolls receiving more than 530 mm of rainfall (Barker, 1981). In contrast, Ustolls of the Great Plains receiving comparable amounts of total rainfall typically have well-developed zones of $CaCO_3$ accumulation within 1 m of the soil surface. The Ustolls receive much of their precipitation during the growing season when evapotranspirational demand is high, resulting in less moisture being available for mobilization of $CaCO_3$. As previously discussed, spatial patterns of carbonate removal and accumulation along hillslopes can often be used to interpret soil hydrology.

33.8.4.3.2 Clay Translocation

The movement and accumulation of clay are common soil-forming processes that occur in soils occupying relatively stable landscape positions and depression-focused recharge depressional basins. Clay translocation causes differences in soil texture that can affect soil water movement and the subsequent genesis of certain soil morphological features. This process is thought to be important in the formation of Albolls. Appreciable clay movement does not occur until carbonates have been removed from the upper portions of the soil profile (Duchaufour, 1982; Fanning

and Fanning, 1989). Carbonate removal releases clay previously cemented, which may be subject to further chemical alteration prior to movement (Fenton, 1983). In calcareous parent materials, subsoil clay accumulation commonly occurs immediately above the zone of $CaCO_3$ accumulation. In Mollisols, subsurface clay accumulation is highly variable and is not always observed.

In a study of Mollisols and associated soils in the forest steppe–dry steppe transition in Eastern Europe and the forest–prairie transition in the United States Great Plains, Bronger (1991) was unable to find micromorphological evidence of clay illuviation in Mollisols commonly described as having argillic horizons. While Nettleton et al. (1969) proposed that the lack of illuvial clay skins in some fine-textured soils was due to disruption by shrink/swell clays, Bronger (1991) suggested that increased clay contents in Mollisol subsoils are either lithologic discontinuities or are polygenetic in origin and, as such, are relict features that formed under past, moister climates. Sobecki and Wilding (1983) investigated Texas Coast Prairie Mollisols and found that argillic horizons were confined to microtopographic lows, suggesting depression-focused recharge. Weakly developed Bt horizons on microtopographic highs were determined to be relict features based on micromorphological analysis. They suggested that processes leading to both carbonate accumulation and clay illuviation in the same horizon were incompatible under the current humid climate.

33.8.4.3.3 *Erosion and Sedimentation*

Erosional processes result in the redistribution of surface soil material from upper to lower hillslope positions. This process often results in thickening of the mollic epipedons in concave slope positions. Soils with these overthickened surface horizons are often classified as cumulic at the subgroup level. Anthropogenically accelerated erosion causes significant reduction in the thickness of upland A horizons, which no longer meet the surface horizon thickness criteria for Mollisols. These eroded soils will typically be classified as Inceptisols or Alfisols (if an argillic horizon is present). Erosional losses as a genetic pathway for Alfisols or Inceptisols, which is contrary to the conceptual models for the genesis of these soils, has been a long-standing taxonomic dilemma in the classification of Mollisols (Fenton, 1983). The choice presented to soil mappers is between recognizing eroded phases of Mollisols, or classifying the soils based on the thinner epipedon resulting from anthropogenically accelerated soil erosion.

33.8.5 Land Use

Human impact on the use of Mollisols has increased dramatically over the past century. Early cultures had little influence on grassland soils other than the use of fire as a management tool. In the plains of North America, burning was used to stimulate the subsequent year's production and attract buffalo (Warkentin, 1969; Anderson, 1987). With the advent of the moldboard plow, Mollisols became widely used as arable soils. During the early 1900s, artificial drainage (tile drains and surface ditching) and

flood protection measures lowered water tables sufficiently for the conversion of extensive areas of Aquolls and other marginally wet Mollisols to productive cropland. In the United States, where Mollisols make up 22% of the land area, much of the agriculturally based, westward settlement was a direct result of the ease with which productive Mollisols could be cleared by fire. The high level of native fertility and favorable physical properties meant that most areas of Mollisols were converted to row cropping. Virgin areas of Mollisols and associated prairies are now quite rare in the United States.

Mollisols are among the most agriculturally productive soils in the world. Although Mollisols make up only ~7% of the Earth's ice-free land area, a large part of the world's wheat and other small grains are grown on Ustolls and Xerolls (Troeh and Thompson, 1993). Because Mollisols are commonly found in subhumid climates, lack of sufficient soil moisture can limit the production of traditional agricultural crops. Soil moisture conservation strategies, such as fallowing and residue management, must be implemented for sustainable dryland farming. Unfortunately, the use of unsustainable farming practices not designed to protect the soil from erosion or to conserve soil organic C has led to a decline in soil quality and subsequent productivity in some regions of the world. Long-term cultivation has reduced the organic C content of Mollisols, and reductions of ~35% in C contents in 60–70 years of cultivation have been documented (Tiessen et al., 1982). These reductions are often associated with degradation of soil structure and increased susceptibility to erosion. More recent research into the impacts of agriculture on the nearly level Aquolls and Udolls in Illinois indicated that these soils are quite resilient. After an initial loss of SOM when the native prairie is cultivated, they retain much of their organic C even after a century of row crop production (David et al., 2009). However, in most cases, the conversion of prairie to cropland further increases the erosion potential and has resulted in devastating wind erosion during cyclic droughts in portions of Asia and North America, most famously in the serious wind erosion of Ustolls during the Dust Bowl in the 1930s. These processes of soil degradation result in loss of organic matter and organically bound nutrients and subsequent declines in soil productivity. The use of appropriate soil conservation practices can greatly reduce soil degradation and maintain soil productivity.

As population pressure has increased, conversion of Mollisols from arable to urban uses increased. Many of the same characteristics that make Mollisols preferable for cropland also favor many nonagricultural uses. The conversion of these prime agricultural soils, and the associated decline in the resource base for food and fiber production, has generated much debate in the United States and stimulated farmland preservation efforts.

33.9 Spodosols

Randall Schaetzl

Willie Harris

33.9.1 Introduction

Spodosols are soils that typify the process of podzolization; they are roughly equivalent to Podzols in older U.S. classifications schemes (Baldwin et al., 1938; Muir, 1961; Petersen, 1976, 1984; McKeague et al., 1983). (The term Podzol is still widely used in many classification schemes outside of the United States.) In the process of podzolization, soluble compounds of Al and organic matter, often accompanied by Fe and Si, are translocated from an upper, eluvial zone to a lower, illuvial zone. As a result, a typical Spodosol profile has a bleached E horizon overlying a dark, reddish to brownish Bs, Bh, and/or Bhs horizon(s). The process is best expressed in humid climates, under vegetation assemblages that tend to produce acidic litter. Spodosols are most extensive in cool-cold climates, but also are common in subtropical and tropical regions, where eluvial and/or illuvial zones can be quite

thick and well expressed (Daniels et al., 1975; Thompson, 1992; Figure 33.58). These thick illuvial zones constitute a substantial pool of C (Holzhey et al., 1975; Stone et al., 1993), one that has not yet been definitively tallied in many estimates of global C stocks.

The original Podzol concept derived from the ashy, light colored E horizon, having been derived from the Russian words "pod" (under) and "zola" (ash) (McKeague et al., 1983; Sauer et al., 2007). This name has often been mistakenly applied to all soils with a light colored, high-chroma E horizon, regardless of the nature of the underlying horizons. Thus, soils with a well-developed E horizon and undergoing various degrees of podzolization needed to be separated from those that embodied the core concept of the true podzolization process. Therefore, in an attempt to restrict the order Spodosols to soils formed mainly via podzolization, the Soil Survey Staff (1975, 1999) placed the taxonomic focus on B horizon character, chemistry, and morphology, for example, Stanley and Ciolkosz (1981), Mokma (1993). Important aspects of the current Spodosol classification scheme for the United States (Soil Survey Staff, 1999) are discussed in the following.

33.9.2 Processes Involved in the Formation of Spodosols—the Podzolization Suite

In podzolization, a combination of organic matter and Al, often in association with Fe^{3+}, are translocated from the upper profile to a lower, illuvial horizon (Petersen, 1976; DeConinck, 1980; Buurman and van Reeuwijk, 1984; Courchesne and Hendershot, 1997, Lundström et al., 2000a). Some literature suggests that podzolization includes not only translocation of metals (sesquioxides) and organic matter, but also the associated processes of (1) chemical weathering by organic and carbonic acids and (2) clay destruction and/or translocation (Fridland, 1958; Schaetzl and Anderson, 2005). Regardless, in both definitions, podzolization processes operate under acidic conditions, where weathering is intense in the upper profile, and where the weathering byproducts are translocated to the B horizon, or removed from the profile. As a result, an acidic E horizon is formed—impoverished in

Al, organic matter and usually Fe. In many soils, the result of podzolization is a profile that classifies as a Spodosol (or Podzol). It is important to note, however, that podzolization is also a subsidiary or background process in many soils. For example, it may occur after, or in association with, acidification, lessivage, brunification, and various intensities of redox processes (DeConinck and Herbillon, 1969; Guillet et al., 1975; Ugolini et al., 1977; Li et al., 1998; Harris and Hollien, 1999, 2000; Hseu et al., 2004).

33.9.3 Characteristics of a Spodosol Profile

Spodosols often have distinct horizons with relatively abrupt or clear boundaries, usually due to low rates of pedoturbation by bioturbators, for example, worms, mammals, insects, which can blur boundaries (Langmaid, 1964), or break and distort them, as occurs locally during tree uprooting (Figure 33.59; Schaetzl, 1986; Schaetzl et al., 1990). Coarse soil textures, acidic conditions, and cool soil temperatures act in unison to retard faunalturbation. It is common for E–Bh horizon boundaries to be wavy or irregular, sometimes conforming to the shapes of previous tree roots, which might have influenced the percolation pathways of water in these sandy soils (Figure 33.60).

Due to the low rates of decomposition more than to high rates of litter production, Spodosols typically have thin to thick (2–20 cm), usually continuous, O horizons. Particularly thick O horizons are found under coniferous forests and heath vegetation. Decomposition rates of the litter decrease with temperature, favoring greater litter accumulation for cool region (frigid and cryic) Spodosols. Slow litter decomposition is also a consequence of the acidic litter character and its high contents of slowly degradable compounds, for example, lignins and waxes (Vance et al., 1986). Spodosol O horizons vary in their degree of decomposition, although Oi and Oe horizons, also referred to as *mor* litter, are common. The slow decomposition in the O horizon is performed by fungi, usually resulting in mycelial mats.

The A horizons in Spodosols are typically thin, especially in coarser-textured soils, where macroorganism activities are low. Bioturbation of organics from the O horizon into the mineral

soil, typically important to A horizon formation, is minimal in Spodosols. Thus, the primary pathways of A horizon formation are via translocation of organic materials into the mineral soil by percolating water and by in situ root decay. Neither of these processes is strong in Spodosols. However, small organic molecules, with varying degrees of solubility, can move through the A horizon and participate in chemical reactions in the middle and lower profile. Many Spodosols lack an A horizon entirely; the O horizon is directly overlying an E horizon.

The E horizon is a morphologic hallmark of the Spodosol order and of podzolization. The E horizon is lighter colored (higher Munsell values) than other horizons in the profile because (1) coatings bound by oxides and organic matter have been stripped from, or inhibited from coating, the quartz grains that dominate the mineralogy and (2) most of the dark, ferromagnesian minerals in the parent material have been chemically weathered. Many Spodosol E horizons are bleached to the point of being almost pure white. The E horizon is commonly the most acidic horizon in the Spodosol profile, having been leached of most of its base cations (Lundström et al., 2000b). It is also coarser textured than underlying horizons, partially due to clay eluviation, as well as intense chemical weathering that destroys some of the clays. Well-developed E horizons qualify as albic horizons (Soil Survey Staff, 1999). Although most Spodosols do have a well-developed, high-chroma E horizons, *Soil Taxonomy* (Soil Survey Staff, 1999) has placed taxonomic emphasis on the illuvial (B) horizon, for two reasons: (1) the E horizon is often disturbed by plowing, bioturbation, or erosion, and (2) in soils formed in loamy parent materials, the E horizon is often not well expressed, although the strong B horizon is clearly indicative of ongoing podzolization (Figure 33.61).

The reddish, reddish brown, or nearly black, B horizon in Spodosols is usually a Bs, Bh, or Bhs, indicative of illuvial sesquioxides, humus, or both (Mokma and Evans, 2000). In Spodosols with a high water table (Aquods), the B horizon may be low in ferrous iron (Fe^{++}) compounds, having been lost to the groundwater. The zone of maximum illuvial humus accumulation in most Spodosol B horizons is near the top, variously decreasing with depth. Thus, Bhs–Bs1–Bs2 horizon sequences are common, as illuvial carbon decreases with depth in the horizon. The upper boundary of B horizons is typically abrupt, often with wavy boundaries or tonguing, contrasting to the typically diffuse lower horizon boundaries (Figure 33.60). The wavy upper boundary reflects the preferential flow of percolating water, as it moves in tongues along preferred zones in coarse-textured soils, or as it follows root pathways (Figure 33.60). Schaetzl (1986, 1990) determined that at least some of these tongues are due to preferential infiltration beneath microtopographic depressions and pits (present or former) in the forest floor. Well-developed B horizons qualify as spodic horizons if they meet certain chemical and morphological criteria (Soil Survey Staff, 1999). Spodic horizons are characterized by illuvial Al and organic matter; more details are provided in Section 33.9.7.

Strongly-developed spodic horizons, for example, Bhsm, Bsm, can be cemented into ortstein (Figure 33.60; Wang et al., 1978; Dubois et al., 1990; Mokma, 1997). Ortstein is commonly so well cemented that it restricts root penetration, but when sandy it still

FIGURE 33.61 Profile of a loamy, mixed, frigid, Typic Haplorthod from Maine. Note the weak E horizon in this soil, despite evidence from the B horizon of intense podzolization and illuviation of humus and Fe. This type of Spodosol morphology is common in parent materials where silt and clay contents are high; in such soils the high surface area limits the rate at which podzolization can "strip" all the particles in the E horizon of their coatings. (Photo by R. Schaetzl.)

maintains good permeability (Lambert and Hole, 1971). Ortstein is generally more planar in Aquods than in better drained soils and is usually associated with a water table (Mokma et al., 1994). The cementing agent in ortstein is generally assumed to be an amorphous, Al-dominated material (Lee et al., 1988), although Fe and Si may also play a role.

33.9.4 Spodosol Genesis: Details and Theories of the Podzolization Process

33.9.4.1 The General Suite of Processes

There are two primary theories of podzolization: (1) the protoimogolite theory and (2) the chelate-complex theory. Both endeavor to explain the mobilization, translocation and immobilization of the oxidized, metal ions (sesquioxides) and organic compounds in soils (Schaetzl and Anderson, 2005), as well as the variability in organic matter content in Spodosol B horizons. By association, podzolization theory must also explain the intense weathering typical of these soils. All podzolization theories assume that the soil parent material has been preconditioned or exists in a state conducive to the process: it has minimal clay and is acidic or has been acidified. It is also assumed that the vegetation produces litter rich in low-molecular-weight organic acids and fulvic acids, and that

the climate is humid enough to initiate deep percolation, at least at some times of the year.

Intense weathering of minerals by organic acids is a central part of the podzolization process (Van Hees et al., 2000). As minerals weather, various cations are released to the soil solution. Base cations must be depleted before Al and Fe can be rendered mobile. If the soil pH is not low enough, that is, if too many base cations exist in the soil, Al and Fe cations released by weathering will precipitate as solid, less mobile forms (oxides, oxyhydroxides, and hydroxides); they will not readily translocate. Defining the exact mechanism by which these metal cations become mobile and illuviate is where the two main theories of podzolization diverge.

The protoimogolite theory focuses on the inorganic, colloidal transport of Al, Si, and Fe. The theory was formulated by the observation that Al and Fe can exist in some humus-poor Spodosols as amorphous, inorganic compounds, for example, imogolite and allophane (Farmer et al., 1980; Anderson et al., 1982; Farmer, 1982; Childs et al., 1983; Gustafsson et al., 1995). Imogolite and allophone are Al–Si hydroxyl gels also known as imogolite-type materials, or ITM (Lundström et al., 2000a). In this theory, ITM form from weathering products in O and E horizons and move with percolating water until immobilized, usually in the B horizon where higher (>5) pH values exist. Al is transported as a positively charged hydroxy aluminum silicate complex (Anderson et al., 1982). The Al and Fe in ITM have presumably been dissolved/weathered by noncomplexing organic and inorganic acids, as well as by readily biodegradable, small, complexing organic acids (Lundström et al., 2000b). Next, negatively charged, colloidal organic matter migrates from the upper profile into the B horizon and precipitates onto the positively charged ITM that are already there. This process is supported by thin section data that show dark organs surrounding allans (allophane-rich cutans) (Freeland and Evans, 1993), or Al- and Fe-rich cutans overprinted onto Si-rich cutans in B horizons (Jakobsen, 1989). Dissolution/weathering processes continue to act on ITM in the B horizon. Because ITM are more easily weathered than crystalline Fe oxides, ITM will continue to eluviate, eventually leaving behind an Fe-rich B horizon, as the lower B horizon becomes enriched in Al by the continued dissolution and remobilization of ITM rich in Al. In a hybrid model of sorts, Ugolini and Dahlgren (1987) and Dahlgren and Ugolini (1991) proposed that ITM are formed in B horizons in situ, as organometallic complexes illuviate and interact with an Al-rich residue or protoimogolite formed thereby CO_2 weathering (Lundström et al., 2000b). Low soil organic matter contents tend to favor the formation of ITM, whereas conditions in soils with abundant organic matter appear to inhibit its formation (Wang et al., 1986).

In the more traditional, widely accepted, chelate-complex (or fulvate complex) theory, organic acids form chelate complexes with Fe and Al cations, rendering these normally insoluble cations (and Si) soluble for translocation (Wright and Schnitzer, 1963; DeConinck, 1980; Buurman and van Reeuwijk, 1984; Dahlgren and Ugolini, 1989; Sauer et al., 2007). Normally, Fe^{3+}

and Al^{3+} are not soluble in soils, but when chelated they become more soluble and are readily translocated in percolating water (Riise et al., 2000). In short, the process is driven by organic acids, as opposed to the dominantly inorganic pathway outlined by the protoimogolite theory.

Organic acids and phenolic compounds in soils generally can be categorized based on their molecular weights: low-molecular-weight (LMW) acids <1000 Da, fulvic acids (FAs) 1000–3000 Da, and humic acids >3000 Da (Krzyszowska et al., 1996; Lundström et al., 2000b). Many of these acids are readily produced during litter decay and carried in the soil solution. They also can be produced as root and fungal exudates. From experiments on aqueous extracts from plant litter, it has been long known that organic acids can dissolve ferric and aluminum oxides (Bloomfield, 1953; Schnitzer and Kodama, 1976; Kodama et al., 1983; Lundström et al., 1995). Many of these acids, however, also readily form metal chelates. Thus, central to the chelate-complex theory is the idea that organic acids produced in soils not only weather primary minerals but also chelate the cations released from them. As the chelate complexes move within the profile, they continue to chelate more metal cations, but remain soluble until a certain level of saturation (metal loading) is achieved (Petersen, 1976). At this point, the complex is rendered immobile and precipitates on ped faces, roots, and mineral surfaces. Immobilization (precipitation) of the chelate complexes occurs for any of a number of reasons: (1) increased pH values in the lower profile (Gustafsson et al., 1995), (2) microbial decomposition of the organometallic complex (Lundström et al., 1995), (3) stoppage of the percolating water at a water table, lithologic discontinuity or aquitard (DeConinck, 1980; Buurman and van Reeuwijk, 1984; Schaetzl, 1992; Schaetzl and Schwenner, 2006), (4) flocculation from continued metal loading and electrostatic charge reduction of complexes (DeConinck, 1980), and (5) sorption/precipitation of complexes within a matrix of finer illuvial materials also accumulated as part of the podzolization process (Holzhey et al., 1975; Dahlgren and Marrett, 1991; Harris et al., 1995; Li et al., 1998; Harris and Hollien, 1999, 2000). Once precipitated in the lower B horizon, aluminum can be released by additional microbial breakdown of the organometallic complexes, or it can combine with silica to form ITM. Iron so released will form less soluble ferric oxyhydroxides (Buurman and van Reeuwijk, 1984). With time, as more organometallic coatings accumulate in the B horizon, cutans on grain surfaces tend to thicken. Because they are not crystalline, the cutans tend to shrink and crack upon drying. Cracked grain coatings are diagnostic of illuvial organometallic compounds (DeConinck, 1980; Stanley and Ciolkosz, 1981).

In the initial stages of podzolization, Fe and Al cations are released from primary minerals (if present) so rapidly that any chelate complexes that form are quickly saturated and hence, immobilized. Eventually, however, a zone of depleted Fe and Al forms (the incipient E horizon). Newly formed organic chelates can then pass through this eluvial zone before becoming saturated. Therefore, the E horizon may be present in the early

stages of podzolization, but not visible until it deepens past the depth of organic matter accumulation, that is, the A horizon. In sandy, upland soils, mixing is so minimal that A horizons are thin, and distinct E horizons can exist immediately below, perhaps within a few millimeter of the surface. Over time, the E horizon thickens, as (1) metal cations are continually stripped from the top of the B, remobilized, and redeposited lower and (2) the base of the E grows downward, below the depth of melanization. The B horizon continues to accumulate organic matter, Fe, and Al as cutans and as microaggregates, but the majority of the illuvial compounds reside near the top of the B horizon.

33.9.4.2 Groundwater Podzolization: Alaquods

Most Spodosols formed by processes described above are found in cool (mesic to cryic), midlatitude sites, on freely draining, upland landscape positions. However, large areas of well-expressed Spodosols also occur in subtropical and tropical regions where podzolization is associated with water tables (Brasfield et al., 1973; Dubroeucq and Volkoff, 1998; Harris, 2000; Watts and Collins, 2008). These Spodosols commonly classify as Alaquods, reflecting their wetter conditions and and prevalence of Al over Fe in the spodic horizon (usually a Bh horizon). In the southeastern United States, these wet Spodosols typically occur on nearly level, Coastal Plain landforms called "flatwoods" (Brasfield et al., 1973; Brooks, 1981). Flatwoods are poorly drained uplands where periodic chemical reduction and leaching favor Fe depletion. Flatwoods vegetation includes pine species (e.g., *Pinus palustrus*; *Pinus taeda*) with an understory dominated by saw palmetto (*Serenoa repens*) and gallberry (*Ilex glabra*) (Abrahamson and Hartnett, 1990), a plant community consistent with podzolization. However, Alaquods are not restricted to this plant community or to flatwoods landscapes. They can be found along some lake margins, seepage zones, floodplains, etc. with the common denominator being a seasonal water table.

A clue to the water table linkage is the morphological transition between Alaquods and better drained soils upslope (Garman et al., 1981; Tan et al., 1999). The common trend is for the thickness and morphological prominence of E and Bh horizons to diminish with diminishing water table influence, for example, shorter periods of saturation, greater depths to saturation, etc. (Figure 33.62). The Bh lightens in color and its upper boundary becomes shallower as the mean water table depth increases. This divergence between Bh horizon and the water table at transitions confirms that Bh horizons in these Alaquods do not form as a simple consequence of C precipitation with groundwater-entrained Al in quartz sand. Instead, true podzolic E horizons form, similar to those in Spodosols of cooler regions. Similarity of cooler and warmer Spodosols is also evidenced by morphological properties such as common irregular upper boundaries, for example, the root disturbance legacy effect on preferential flow as discussed above (Figures 33.59 and 33.60). Furthermore, near-surface water saturation
FIGURE 33.62 Schematic of a transition between Paleudult and Alaquod. Fading-upward of Bh and wedging out of E is typical of transitions between Aquods and better drained soils in northern Florida (Garman et al., 1981; Tan et al., 1999). The E of the Paleudult has sufficient coatings on sand grains to impart lower values and higher chromas than for the Alaquod E, in which grains have been essentially stripped of coatings.

is a dynamic seasonal condition rather than a static condition that would be required to explain abrupt white-to-black horizon boundaries.

The E–Bh boundary in Alaquods is also a boundary between zones of uncoated sand grains (A and E horizons) and coated grains (Bh and subjacent horizons; Figure 33.62). Sand-grain coatings are either stripped or prevented from forming in the upper profile under typical Alaquod hydrology, yet coatings occur in near-surface horizons of better drained sandy soils of the region (Harris et al., 1996). Hence, the origin, composition, and stability of grain coatings are pertinent to the mechanism of Alaquod formation. These coatings likely originate from mineral weathering in conjunction with the binding effects of secondary metal oxides. Most <50 μm-sized minerals in these soils are bound in coatings. The clay fraction of grain coatings in the Coastal Plain soils of the southeastern United States is commonly dominated by hydroxy-interlayered vermiculite, kaolinite, gibbsite, and quartz (Carlisle and Zelazny, 1974; Harris et al., 1987a, 1987b), with minor amounts of metal oxides that bind the coatings. These minerals, except for quartz, are nearly depleted in podzolic E horizons.

Experimental generation of Aquod-like E–Bh horizons has documented that colloidal transport, that is, eluviation–illuviation of sand-grain coatings, was a component of the process (Harris et al., 1995; Harris and Hollien, 2000). The coating destabilization occurred as a result of organo-complexation of the metal oxide-binding agents. Sand-grain stripping produced a light-gray podzolic E horizon and culminated in illuviation of the mobilized sand-grain coating materials to form a finer-textured zone subjacent to the E horizon. The illuvial zone (incipient Bh) provided conditions for sorption of organometal complexes and thus served as a template for Bh horizon development. The E–Bh horizon boundary contrast sharpened with time, from the darkening effect of continued C flux.

Colloidal transport in experimental formation of Aquod-like features does not prove that it occurs in the genesis of real Alaquods. However, it is consistent with the (1) crystalline clay mineralogy of Bh horizons, which typifies that of sand-grain

coatings in nonpodzolized areas (Harris and Carlisle, 1985; Harris et al., 1987a; Harris and Hollien, 2000), (2) upward-trending Bh horizons in areas transitional to better drainage, as described above (Figure 33.62), (3) elevated silt and clay contents in Bh horizons, and (4) abrupt, irregular E–Bh boundaries that can be more easily accounted for by the physical accretion of fine particulates than by chemical precipitation alone. Indeed, other studies have reported evidence of particle migration in Spodosols (Calhoun and Carlisle, 1973; Guillet et al., 1975; Ugolini et al., 1977; Li et al., 1998; Harris and Hollien, 1999).

The role of the water table in Alaquod formation may be to bring about conditions unfavorable for the stability or formation of sand-grain coatings. Artificial generation of E- and Bh-like horizons was achieved only (1) in predisposed coated sands collected on wetter landscape positions, that is, bordering Alaquods, and (2) under fluctuating water table conditions (Harris et al., 1995). Lower Fe oxide contents and lower Al crystallinity are factors that could explain the predisposition of wetter landscape materials to form Aquod-like features, compared with materials from drier summit positions. Lower Fe contents would be a predisposing factor for sand-grain coating destabilization because Fe oxides serve as binding agents. Aluminum oxides were not depleted in predisposed materials and still served to bind coatings. However, the lower crystallinity of Al oxides, possibly the result of higher organic acid activity in the wetter positions, would render them more vulnerable to organic acid complexation (Huang and Violante, 1986). Thus, wetter landscapes predispose sand-grain coatings to undergo destabilization and to participate in podzolization processes theorized above, should the groundwater influence intensify.

A fluctuating water table is still required to experimentally form artificial E–Bh sequences, even in predisposed material. Hence, the water table appears to have a role in not only predisposing, but also actually triggering, podzolization. The triggering mechanism, however, is still uncertain. It may relate to the effects of the frequency and duration of water saturation in the affected zone. For example, anaerobic conditions could inhibit microbial degradation of complexing organic anions, such that these anions reach sufficient activity to mobilize metals.

33.9.4.3 Groundwater Podzolization: Deep, Thick Bh Horizons

The previous discussion on Alaquod formation conforms closely to the chelate-complex theory of podzolization. However, the formation of deep, thick Bh horizons, found in some subtropical coastal regions (Daniels et al., 1975; Thompson, 1992), may involve elements of the protoimogolite theory. These horizons are morphologically distinct from shallower, thinner Bh horizons (Figure 33.60) and their upper boundaries may be located within, or below, 2 m. There are sometimes multiple Bh horizons with varying degrees of coalescence, across zones up to several meters thick. Deep Bh horizons of some regions (1) darken gradually from the upper boundary downward, rather than being

darkest at the top, (2) are not overlain by a well-expressed podzolic E horizons, (3) have consistently smooth upper boundaries, and (4) transgress soil drainage continua, extending below excessively drained sandy soils, as well as Alaquods. These distinctions suggest C immobilization by *in situ* inorganic Al (Farmer et al., 1983) at the approximate upper boundary of long-term saturation, adhering to the independent C-transport aspect of the latter theory. The absence of a well-expressed podzolic E horizon is evidence that immobilization of C by Al, as influenced by water table, could occur whether there has been C-induced transport of Al or not.

33.9.5 Factors That Influence the Formation of Spodosols

Podzolization occurs in humid climates, where precipitation exceeds evapotranspiration during some of the year, such that water frequently percolates through the profile, or stands in the profile at the water table (McKeague et al., 1983). Podzolization is best expressed under vegetation that produces acidic litter, such as coniferous forest and heather, and on coarse-textured parent materials that have minimal surface area. It is especially strong in the coniferous forests of the high midlatitudes. Cool temperatures in midlatitude and alpine areas keep evapotranspiration rates low and inhibit decomposition of the acidic litter. The discussion below focuses on how, as these factors change, the character of the profile also changes.

33.9.5.1 Vegetation

Podzolization is promoted under vegetation that produces acidic litter that decays slowly. The litter decay products, that is, organic acids of various kinds, not only help weather Fe- and Al-bearing primary minerals, but also can be efficient as metal chelates, because they release abundant amounts of water-soluble organic acids. Vegetation types that particularly promote podzolization include heath (heather), hemlock (*Tsuga canadensis*), kauri (*Agathis australis*), and pine (*Pinus* sp.), the litter from which releases acidic leachates (Bloomfield, 1953; Mackney, 1961; Nielsen et al., 1987a, 1987b; Madsen and Nørnberg, 1995; Mossin et al., 2001; Jongkind et al., 2007). Thick litter layers in various states of decay are typical in naturally vegetated Spodosol landscapes. Thick O horizons also help reduce variation in soil moisture contents and allow for more prolonged weathering and leaching of the mineral soil below. Barrett (1997) illustrated the importance of above-ground vegetation to podzolization by demonstrating that the process markedly slows after only a few decades of forest removal and litter disturbance (see also Hole, 1975).

Fire impacts Spodosol development by eliminating or reducing the O horizon volume, changing its chemistry and character, and altering the above-ground forest vegetation. Mokma and Vance (1989) observed that soils under vegetation that burns more frequently were much less developed than in areas of diminished fire frequency. Indeed, in parts of Michigan,

repeated (ca. 5–50 years) fires have so retarded spodic development that most of the soils are Entisols, even after 15,000 years (Schaetzl et al., 2006). Schaetzl (2002) also noted that the areas in Michigan having maximal fire frequencies and minimal soil development also receive much less snow than other areas with better soil development, suggesting that snowpack and snowmelt impacts on soils development are often as important as fire frequency. Indeed, the two are often mutually reinforcing. Subtropical Alaquods are an exception to the fire-suppressing effect on podzolization; they predominate in fire-maintained flatwoods ecosystems.

Because most Spodosols form under forest vegetation, mixing by tree uprooting is a common, albeit localized and often pedon-specific, form of disturbance (Dunn et al., 1983; Schaetzl et al., 1990; Jonsson and Dynesius, 1993). Pit and mound topography is the common surface expression of this process, remaining on the landscape for centuries after the treethrow event (Figure 33.59; Schaetzl and Follmer, 1990; Kabrick et al., 1997; Small, 1997). This microtopography dramatically impacts infiltration pathways, directly and indirectly (Schaetzl, 1990). Soils are often much better developed beneath pits, where infiltration is focused, and litter and snowpacks are thicker. Tree uprooting distorts, breaks, mixes, and even inverts soil horizons, leading to high levels of soil spatial variability (Veneman et al., 1984; Schaetzl, 1986; Meyers and McSweeney, 1995). The spatial variation in soil development continues to evolve and even strengthen as a consequence of the subsequent microtopography and its effects on the redistribution of water and litter.

33.9.5.2 Climate

Spodosols on upland sites are best developed in cool, humid, continental climates, especially those with a pronounced, snowy winter. Cool temperatures favor vegetation types, for example, conifers and heather, that produce acidic litter, which promotes podzolization. Low (but not freezing) mean annual temperatures, coupled with an extended period of subfreezing temperatures and snow in winter, tend to slow litter decay processes and maximize the potential for organic acid production and its slow, steady translocation into and through the mineral soil. Wet local conditions in the tropics similarly affect litter decay, promoting Spodosol development. In warmer and/or drier climates, much of the litter is quickly oxidized and mineralized, resulting in minimal amounts of acid leachate for podzolization. Globally, podzolization and spodic development (on upland sites) is maximal in the frigid soil temperature regime, eventually weakening at the extreme cold end of the climate spectrum, in the gelic and pergelic soil temperature regimes. Here, vegetation transitions to tundra, and soils are frozen for longer periods of time. Similarly, podzolization on upland sites is weak in the slightly warmer, mesic soil temperature regime, where litter decay is rapid and where forest vegetation tends to include more broadleaf trees and base cyclers (Cann and Whiteside, 1955; Schaetzl and Isard, 1991). For example, in midlatitude locations near the "warm" end of their range, Spodosols located on slightly cooler sites tend to be better developed, especially with regard

to B horizon character (Stanley and Ciolkosz, 1981). In the frigid soil temperature regime of northern Michigan, Hunckler and Schaetzl (1997) observed much better spodic development on cooler, northerly slope aspects. Thus, climate impacts podzolization mainly by affecting the vegetation that occupies the landscape and by impacting the nature of the pedohydrologic cycle.

In midlatitude areas, Schaetzl and Isard (1991) observed that podzolization is much more pronounced in areas that receive heavy, early snowfall, and accumulate thick snowpacks. This pattern suggests that snowpacks insulate the soils from freezing (Isard and Schaetzl, 1995), facilitating slow and steady infiltration during spring snowmelt. Snowmelt water is often rich in organic acids, having just percolated through fresh and slightly decomposed litter (Schaetzl and Isard, 1996). Additionally, areas with deep snowpacks have warmer soils, especially in winter, which foster weathering of primary minerals and release of metal cations to the soil solution (Isard et al., 2007). The melting snow also provides water for long, steady infiltration events, and thus, efficient translocation of metal chelates. In support of this assumption, Schaetzl (1990) observed that soil water during snowmelt contained more Fe and Al than water similarly sampled during warm season percolation events. Thicker snowpacks also reduce fire frequencies; fire has been shown to inhibit podzolization in some areas, as previously discussed.

33.9.5.3 Parent Material

Spodosols form best on acidic, coarse-textured parent materials, with low amounts of silicate clay and Fe-rich minerals. In these materials, base and metal cations are slowly released by weathering, and the metal cations are subject to chelation by organic acids in the profile and translocation to the B horizon. (The fate of base cations is varied; many are leached from the profile, some are biocycled.) In finer-textured, Fe-rich soils, cations (especially Fe) are released in abundance, although many are quickly adsorbed to clay minerals. As such, lessivage (clay translocation) and/or brunification (reddening), rather than podzolization, tends to dominate the pedogenic suite. Essentially, the great numbers of Fe and other cations released to the soil solution in these types of parent materials commonly overwhelm the ability of the soil to translocate them. As a result, distinct eluvial/illuvial zones do not readily form (Duchaufour and Souchier, 1978; Alexander et al., 1994; Figure 33.61). These soils commonly only exhibit a reddened, "color B" horizon with no, or only a thin, E horizon. Thus, as clay and Fe contents increase, translocation of metal cations and humus decreases and E horizons are less "bleached" (Cline, 1949; Gardner and Whiteside, 1952). Schaetzl and Mokma (1988) used this knowledge to develop a numerical, field- and morphology-based index of spodic development—the POD index.

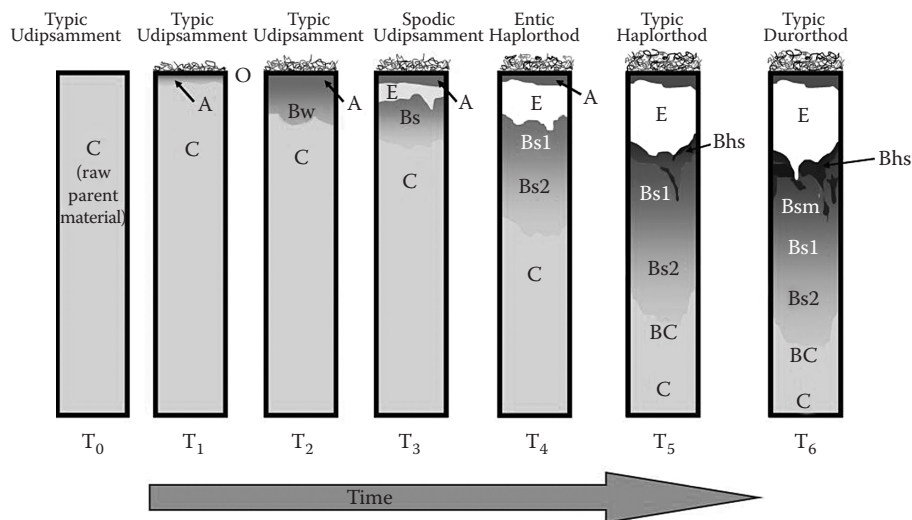
Increased biological activity in finer-textured soils also makes it more difficult to retain a thick O horizon at the surface. Particularly, important is the increased amount of bioturbation in these finer-textured soils, which can blur or destroy incipient horizons. Basic (high pH) parent materials must generally be leached of free carbonates before podzolization can


FIGURE 33.63 Typical horizonation/soil development sequence, from Entisols to well-developed Spodosols, on sandy, well-drained parent materials in the midlatitudes.

begin in earnest, as high pH values inhibit the formation of metal–chelate complexes and inhibit weathering and release of metal cations. Thus, podzolization will occur sooner in parent materials that are initially acidic. Coarse-textured parent materials also foster rapid infiltration and deep percolation, accelerating the development of an eluvial zone, and a deeper B horizon.

33.9.5.4 Time

Spodic morphologies develop along generally predictable pathways (Figure 33.63) and can form in as few as a few decades (Paton et al., 1976; Stützer, 1998), although it usually takes at least 3000–8000 years, under optimal conditions, for this development to reach the point where the soil classifies as a Spodosol (Franzmeier and Whiteside, 1963; Jauhiainen, 1973; Barrett and Schaetzl, 1992; Mokma et al., 2004; Sauer et al., 2008). E horizons typically form first, or are most apparent, often forming within a few centuries (VandenBygaart and Protz, 1995; Lichter, 1998; Barrett, 2001). Noticeable darkening and reddening of the B horizon take longer to occur, but is often visible within 1000–2000 years. After the Bs horizon has become well established, a Bhs horizon may form near the top of the illuvial zone. A chronosequence in beach deposits in Norway (Sauer et al., 2008) showed incipient podzolic features within 3800 years, but fully expressed spodoc horizons were observed only in the 6600-year-old soil. In some soils, cementation of parts of the B horizon (ortstein) may follow. Sauer et al. (2007) provide an excellent review of the rate of Spodosol formation.

33.9.5.5 Topography, Relief, and Drainage Class

In this chapter, we have differentiated between cool region Spodosols that commonly occur on freely drained upland landscape positions and subtropical Spodosols that are mainly restricted to wet upland landscapes. The commonality is "upland;" Spodosols, regardless of drainage, are located on

landscapes that experience leaching and throughflow of soil water. Flatwoods of the southeastern United States are an example of poorly drained, leached uplands. However, some poorly drained leaching soil environments are not uplands, for example, toeslopes of sandy hills, and lake margins. There is a strong hydrologic–topographic control of Spodosol occurrence in the southeastern United States. Spodosols dominate on landscapes with fluctuating water tables but are absent, or only of isolated occurrence, on other landscapes, for example, sandhills, karst terrain. Podzolization in all settings involves gravity-driven translocation, which can also be affected by preferential flow. Materials move from eluvial to illuvial horizons and, barring disturbances such as tree uprooting or bioturbation, and excluding cation biocycling, do not readily move back toward the surface, even in wetter Spodosols. Indeed, Schaetzl and Mokma (1988) found that Spodosols in somewhat poorly drained positions were generally the best developed Spodosols, among drainage classes. Further, Alaquods can have strongly expressed E horizons (Watts and Collins, 2008).

33.9.6 Distribution of Spodosols

When considered geographically, the state factors discussed previously outline the global distribution of Spodosols. Thus, Spodosols occur mainly in cool, humid climates, generally under forest vegetation and on freely draining parent materials (Figure 33.58). The most widespread and dense concentrations of Spodosols occur in Canada and the northern Great Lakes region, Russia, Scandinavia and northern Europe. At appropriate (high) elevations, Spodosols are found on just about all of Earth's major mountain ranges. Aquods are also common on wet landscapes of the humid and subhumid tropics and subtropics. In areas where the climate or vegetation is marginal for the formation of well-developed Spodosols, weakly developed Spodosols or soils with spodic-like profiles can still be observed,

provided the remaining state factors favor podzolization. For example, Spodosols exist in cold, polar deserts (Ugolini, 1986; Blume et al., 1997).

33.9.7 Characteristics and Classification of Spodosols

Most Spodosols meet the NRCS classification criteria by having a spodic horizon. The spodic horizon is characterized by illuvial accumulations of Al and organic matter, most of which is translocated from overlying eluvial horizons above, and accumulates in amorphous forms. Illuvial Fe is usually associated with the Al and organic matter, although Fe is not necessary to meet many of the various worldwide "spodic/podzol" classification criteria. These illuvial substances, rich in Al, Fe, and various forms of illuvial organic materials, are referred to as "spodic materials." By definition, spodic horizons must be composed of 85% or more spodic materials (Soil Survey Staff, 1999). The spodic material concept embodies the podzolization process by requiring the materials to have (1) relatively low pH values and high organic matter contents and (2) red colors (usually) if they underlie an albic (E) horizon. In soils that lack an albic horizon, the pH, organic matter content, and color criteria are still required, but the spodic materials must *also* exhibit one or more of the following properties: (1) cementation, (2) cracked coatings on sand grains, (3) significantly more Al and Fe than an overlying horizon, determined by ammonium oxalate extraction, or (4) high optical densities of the liquid ammonium oxalate extract (an indication of amorphous materials, especially organic matter; Stanley and Ciolkosz, 1981; Daly, 1982; Mokma, 1993).

Many soils with a spodic horizon also have andic properties and are placed in the Andisol order (Flach et al., 1980; Soil Survey Staff, 1999). Because Andisols and Spodosols are pedogenically similar, many Andic subgroups of Spodosols have been defined (Table 33.44), and vice versa. Provision is also made for soils in which the spodic horizon is shallow and thus has been plowed. If the Ap horizon of such soils contains 85% or more spodic materials, the soil may classify as a Spodosol instead of an Andisol.

Some Spodosols have only a placic horizon, or a placic and a spodic horizon. The placic horizon is a thin (1–25 cm thick), black to dark reddish, cemented pan with a sharp upper boundary but diffuse lower boundary; it is cemented by Fe (or Fe and Mn) and organic matter (Clayden et al., 1990; Hseu et al., 1999). The pan is often wavy and even may bifurcate. Placic horizons may form as reduced iron, mobilized in surface horizons, is translocated downward in the profile and

oxidized and precipitated in the B horizon. This precipitated Fe can adsorb soluble organic matter, but not necessarily form organometallic complexes (Hseu et al., 1999, Soil Survey Staff, 1999). The iron is usually present as ferrihydrite and poorly crystalline goethite. Placic horizons typically form in soils at landscape positions where conditions change from reducing to oxidizing. The reducing conditions, necessary for placic horizon genesis, are associated with (1) high rainfall and cool temperatures, typical of perhumid climates (and often also associated with Histosols) and (2) a slowly permeable subsurface layer (Lapen and Wang, 1999).

33.9.7.1 Taxonomic Groupings of Spodosols

In a review of Spodosols, Rourke et al. (1988) commonly referred to a "warm" (thermic, hyperthermic, or isohyperthermic temperature regimes) vs. "cold" (frigid, mesic, or isomesic temperature regimes) Spodosol dichotomy. Although this level of distinction is not taxonomically observed at the suborder

or great group level, we agree it is a useful way of considering Spodosols because, globally, these soils are mainly found in two distinctly different climatic settings: subtropical/tropical and cool-cold midlatitude locations. In subtropical and tropical locations, they tend to be located on wet sites (Goldin and Edmonds, 1996), whereas in cooler locations Spodosols occur in all landscape positions. Most "warm" Spodosols are Aquods, Orthods, and Humods; many of these soils lack a Bs horizon and have Bh horizons instead (Rourke et al., 1988). "Cool" Spodosols tend to have thinner profiles, and Bs, Bh, and/or Bhs horizons. Table 33.44 provides a complete listing of the suborders, great groups, and subgroups of Spodosols. Figure 33.64 shows the typical profile morphologies for the most common Spodosol subgroups (Soil Survey Staff, 1999).

33.9.7.1.1 Orthods

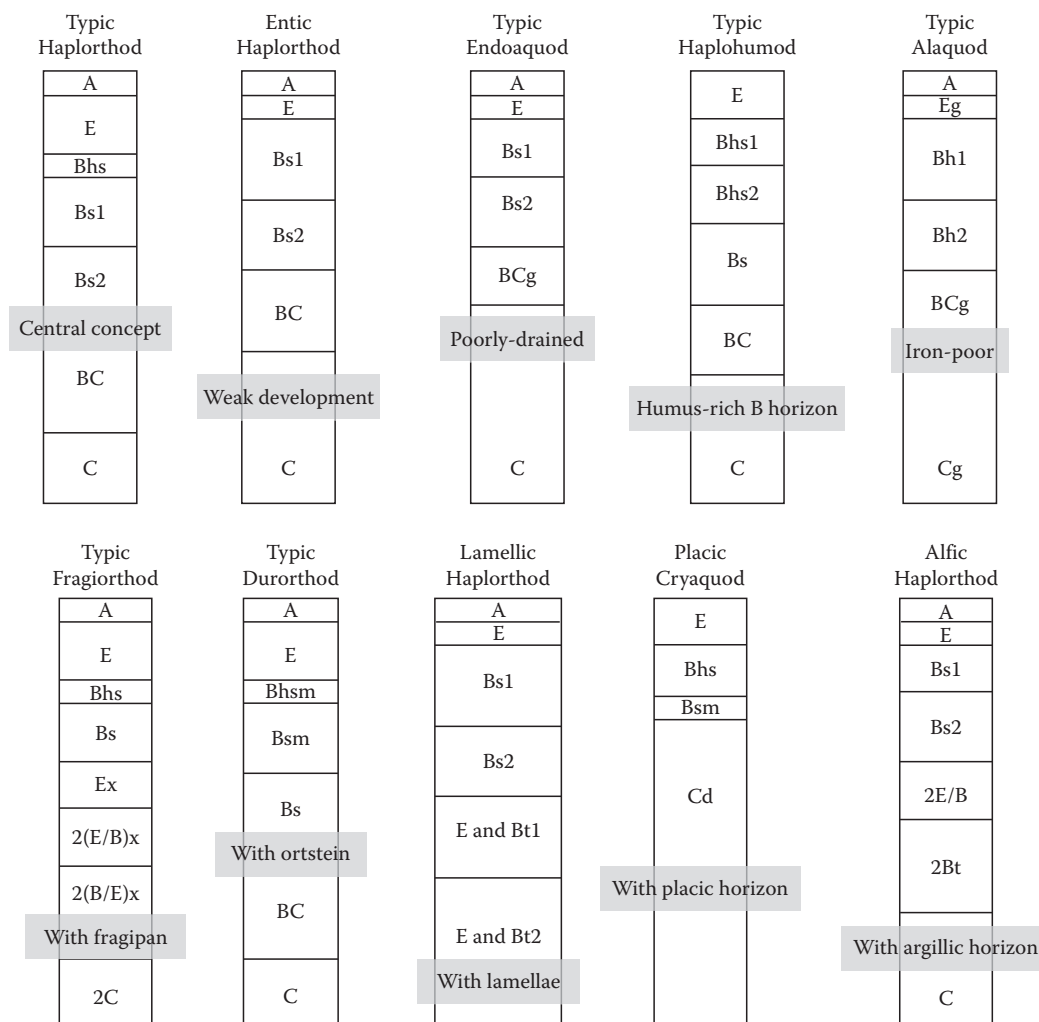
Orthods are the most common Spodosol suborder (Rourke et al., 1988). They typically have A–E–Bhs–Bs–BC–C horizon


FIGURE 33.64 Typical horizonation patterns in common Spodosol profiles, illustrating the variations found naturally in extragrade and intergrade subgroups. Natural undulations in horizon boundaries, as well as O horizons, have been omitted to keep the diagrams simple and straightforward.

sequences, although the Bhs horizon is usually lacking in weakly developed pedons (Base and Brasher, 1990; Schaetzl, 2002).

33.9.7.1.2 Aquods

Aquods have a shallow, often fluctuating, water table. They are the most prevalent Spodosol suborder in subtropical and tropical regions and are a common admixture in other Spodosol landscapes in low-lying landscape positions.

33.9.7.1.3 Humods

Humods have high organic matter contents in the B horizon, usually concentrated in the upper B. In mesic and colder climates, Humods are most common in areas with very humid climates and lush vegetative growth.

33.9.7.1.4 Cryods

Cryods are Spodosols with a cryic soil temperature regime and include soils that have a mean annual temperature <8°C, but lack permafrost.

33.9.8 Management of Spodosol Landscapes

Many Spodosol landscapes are in natural or managed forest systems, where harvest of forest products, recreation, and tourism are the major economic activities. The cool climate of these landscapes, coupled with low soil fertility and sandy textures, tends to limit agricultural options on Spodosols. Particularly, restrictive are the low pH values of these soils, as well as low CEC and available P levels. Many Spodosols adsorb P and K, thereby restricting the ability of plants to obtain these nutrients (Bartlett and McIntosh, 1969; Bartlett, 1972; Villapando and Graetz, 2001). Some types of agriculture have been successful on Spodosols, particularly potatoes, small grains such as rye and barley, some hay crops, and irrigated berries, in some areas, especially where the soils are sandy loam or finer in texture. Blueberries are particularly well suited to cool, acid, sandy Aquods. A long growing season and climatic suitability for high value crops, for example, citrus, warm season vegetables, etc., makes it economically feasible to manage subtropical Spodosols (mainly Aquods) for intensive agriculture or horticulture (Harris et al., 2010). In these agricultural systems, management for some crops requires artificial drainage. Managing Aquods to minimize environment impacts of agricultural P is a challenge due to the minimal P retention capacity of their A and E horizons (Harris et al., 1996) that can result in P transport to water bodies (Allen, 1987; Mansell et al., 1991).

33.10 Aridisols

H. Curtis Monger

Randal J. Southard

Janis L. Boettinger

33.10.1 Concept of Aridisols

Vast areas of the Earth, roughly one-third of the total land surface, are in arid regions. Such aridity results from their position relative to mountain ranges that scavenge moisture, their latitude around 30° where convective Hadley cells create enduring high pressures, or their great distances from large bodies of water (Ahrens, 1991; Figure 33.65). Rainfall in these dry climates is insufficient to maintain perennial streams, and the soils typically have little organic matter, contain pedogenic carbonate, and because their soil profiles are of the "nonflushing type"

(Rode, 1962), contain soluble minerals otherwise leached from humid soils (Southard, 2000). The dominant soil order in arid regions is the Aridisol order, which, with the exception of the Entisol order, covers more of the Earth's surface than any soil order in the *Soil Taxonomy* system (Wilding, 2000).

The central idea of Aridisols is that they do not have water available to mesophytic plants for long periods. This lack of soil moisture may be exacerbated by low water-holding capacity due to a shallow soil depth or restricted infiltration or by low osmotic potential due to salinity. The lack of water also inhibits soil formation.

33.10.1.1 Aridisols vs. Desert Soils

As the order name implies, Aridisols are associated with arid climates, but not all soils in arid regions are Aridisols. In fact, Aridisols occupy less than half of the arid land area (Figure 33.65). Other soil orders in arid climates are the Entisols, Vertisols, Oxisols, and Andisols (Table 33.45). The rationale for having Entisols in arid climates was to preserve the *azonal* concept, which identified soils lacking genetic horizons regardless of the bioclimatic zone in which they occur (Smith, 1986). The rational for having Oxisols in arid climates was that oxic properties, even if irrigated, would remain limiting and the management difficulties would be similar to other Oxisols; thus, they should grouped together with other Oxisols despite their occurrence in dry climates (Smith, 1986). Similar reasons were presented for the shrink–swell properties of Vertisols and the andic properties of Andisols. In some minor areas within the aridic moisture regime, there are soils with a mollic epipedon. These soils are grouped with the Mollisols rather than Aridisols (Smith, 1986; Ahrens and Eswaran, 2000).

33.10.1.2 History of the Aridisol Order

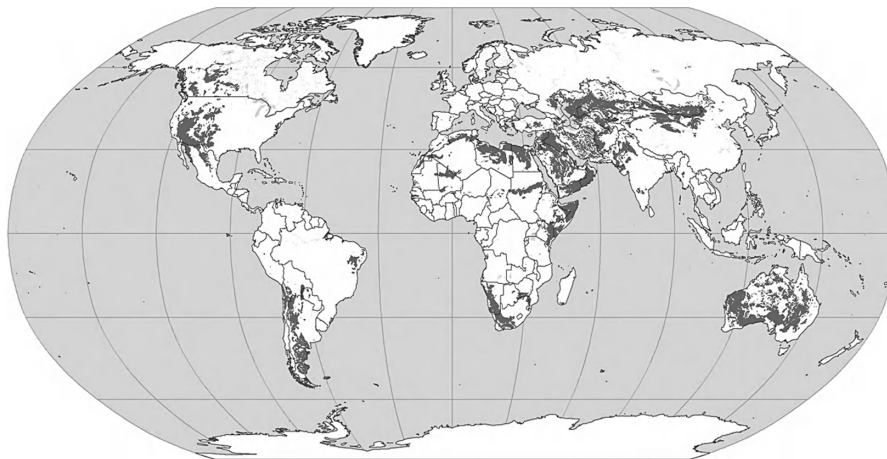
The rationale for the Aridisol order of *Soil Taxonomy* was to separate on a soil map the "sown from the unsown"; that is, the land that can be cultivated from the land that can only be grazed (Smith, 1986). Using climate as the basis for a soil order is somewhat unique to the *Soil Taxonomy* system. Other classification


FIGURE 33.65 Global distribution of Aridisols. (Courtesy of USDA-NRCS, Soil Survey Division, World Soil Resources, Washington, DC, 2010.)

TABLE 33.45 Global Extent of Aridisols (km²) and Vertisols, Oxisols, Andisols, and Entisols Occurring within the Aridic Soil Moisture Regime

Soil Order	Suborder	Africa	Asia	Australia/ Oceania	Europe	South America	Central America	North America	Caribbean	Global
Aridisols										14,264,316
	Cryids	549	398,041	—	100	142,088	—	516,759	—	1,057,537
	Salids	138,542	954,801	69,044	7,993	28,304	—	9,988	31	1,208,703
	Durids	—	—	—	—	—	—	—	—	—
	Gypsids	308,871	298,414	—	1,806	—	—	—	—	609,091
	Argids	292,435	1,107,480	1,395,126	66,339	471,738	2,039	1,012,842	1,446	4,349,445

systems, such as the World Reference Base, do not have an equivalent to the Aridisol order (IUSS Working Group WRB, 2006). Yet the delineation based on climate was inherited from the concept of *zonal* soils, the idea that certain kinds of soils are associated with certain kinds of bioclimatic zones—a concept developed by N.M. Sibirtsev in the late 1800s (Sibirtsev, 1898; Buol et al., 1980).

By the mid-1930s, soils in the arid zone of the United States were mapped as "northern gray desert soils" and "southern gray desert soils" (Marbut, 1935). With the publication of a revised classification system in 1938, the northern gray desert soils were changed to "sierozems" and the southern desert soils, which were associated with creosotebush, were changed to "red desert soils" (Baldwin et al., 1938). With the publication of *Soil Taxonomy* (1975), these soils became Aridisols with two suborders: Argids, if an argillic or natric horizon was present, or Orthids if not (Witty, 1990). In the 1980s and 1990s, the International Committee on Aridisols (ICOMID) developed seven suborders based on important diagnostic horizons and temperature: Cryids, Salids, Durids, Gypsids, Argids, Calcids, and Cambids.

33.10.1.3 Concept of the Aridic Moisture Regime

The concept of the aridic moisture regime is not totally synonymous with the definition of *arid*, which has several definitions. *Arid* in some definitions is based on precipitation alone, as in the arid-semiarid boundary at 250 mm of annual rainfall (Bull, 1991). In other definitions, the arid boundary is based on a combination of precipitation and temperature, as in the aridity index of 10 (Schmidt, 1979). Still, other definitions, such as the Köppen system, combine precipitation, temperature, and seasonality of precipitation (Strahler and Strahler, 1987). In contrast, the soil moisture regime is based on the number of days a soil is dry (i.e., soil moisture held at tensions less than −1500 kPa). Soil moisture is used because the availability of soil

moisture to plants is affected by runoff–runon, infiltration, and available water-holding capacity rather than annual precipitation per se. Generally speaking, however, most soils that have an aridic moisture regime do occur in areas of arid climates (Soil Survey Staff, 1999). Exceptions include semiarid soils with physical properties that keep them dry, such as physical crusts that prevent infiltration, steep slopes where runoff is high, low water-holding capacity in shallow soils, or low osmotic potential in strongly saline soils.

The aridic moisture regime is based on the duration of dryness in the *soil moisture control section* during the period the soil is warm enough for plant growth. The soil moisture control section will vary among soils because it is based on how deep water infiltrates. The top boundary of the soil moisture control section is the depth reached by the wetting front when 2.5 cm (1 in.) of water is applied for 24 h. The bottom boundary is the depth reached by the wetting front when 7.5 cm (3 in.) of water is applied for 48 h. Because these depths are largely a function of soil texture, finer-textured soils, such as those with fine-loamy, coarse-silty, fine-silty, or clayey textural classes, have moisture control sections that lie between approximately 10 and 30 cm (Herbel and Gile, 1973). In contrast, coarse-loamy soils have moisture control sections roughly between 20 and 60 cm, and sandy textural classes have boundaries between approximately 30 and 90 cm depending on coarse fragments, which deepen these limits for all textures.

By definition, a soil has an aridic moisture regime if that soil's control section is dry more than half the year (in normal years) when the temperature at 50 cm is above 5°C. The criterion of "above 5°C" was added because cold temperatures, rather than dryness, can be the limiting factor to plant growth (Smith, 1986). Additionally, the soil moisture control section is "Moist in some or all parts for less than 90 consecutive days when the
FIGURE 33.66 Soil with an aridic soil moisture regime. The moisture control section (10–30 cm) is dry for over 50% of the time in "normal years" (Soil Survey Staff, 1999). The year 1962, however, was not a normal year and does not meet 50%-dry criterion. Neither did it meet the criterion that the soil cannot be moist for more than 3 months (90 consecutive days). The temperature at 50 cm is above 5°C and 8°C (Soil Survey Staff, 1999). Moisture data from Herbel et al. (1994). Temperature data from Gile and Grossman (1979). Soil is a fine, mixed, superactive, thermic Ustic Calciargid. (From Soil Survey Staff. 1999. Soil taxonomy—A basic system of soil classification for making and interpreting soil surveys. USDA agriculture handbook no. 436. USDA-SCS. U.S. Government Printing Office, Washington, DC.)

soil temperature at 50 cm is above 8°C" (Soil Survey Staff, 1999). In other words, if a soil is moist, "not dry" (i.e., water held at tensions greater than −1500 kPa), for more than 3 months (90 consecutive days), the soil is too moist to have an aridic moisture regime. A graphical illustration of an aridic soil moisture regime is shown in Figure 33.66.

33.10.2 Geographical Distribution

The total ice-free land area on Earth is 130,268,185 km². Of that area, 20% or 26,324,771 km² is occupied by soils that occur within the aridic moisture regimes. Aridisols occupy about half (54%) of this area (Table 33.45; Figure 33.65). The rest is occupied by Entisols (43%), Vertisols (3%), Oxisols (0.1%), and minute amounts of Andisols (0.005%) with even smaller areas of Gelisols and Mollisols not shown in Table 33.45. Of the total extent of Aridisols, most (41%) occur in Asia, stretching eastward from the Middle East to northern China (Figure 33.65). Africa contains the next largest extent of Aridisols (21%), followed by Australia (16%), North America (13%), South America (8%), and 1% or less in Europe and Central America. In Asia, most suborders are Calcids, Argids, and Cambids that occur in northern China, Mongolia, Kazakhstan, Iran, Afghanistan, Pakistan, Iraq, and Saudi Arabia, with smaller amounts of Salids in Uzbekistan, Turkestan, and Iran, and Gypsids in localized areas throughout Asia, especially Syria and Turkey. Extensive areas of Cryids exist in the higher elevations of China and Mongolia. Substantial areas of Cryids also exist in North and South

America where they occur at both high elevations and high latitudes. Africa, Australia, North and South America all have expansive areas of Calcids, Argids, and Cambids with smaller areas of Salids and Gypsids, which also occur in a few areas of southern Europe (Eswaran and Zi-Tong, 1991).

Aridisols in mountainous regions form complex patterns with semiarid soils that have ustic and xeric moisture regimes at higher elevations and in topographic low-lying areas that receive run-on water. These topographically controlled soil patterns are also influenced by seasonality of precipitation. For example, in North America, the most southerly Aridisols occur in the subtropical high pressure belt that receives most of its precipitation in the summer from subtropical convective thunderstorms and border the ustic soil moisture regime. Farther north, Aridisols of the intermountain west occur in more continental climates, but precipitation is still dominated by summer thunderstorms driven by orographic lifting in the Rocky Mountains. To the west, Aridisols of the Great Basin region receive most of their precipitation in the winter from Pacific frontal storms and have Aridisols that border the xeric moisture regime.

33.10.3 Diagnostic Horizons and Classification

33.10.3.1 Epipedons

Virtually, all Aridisols have the ochric epipedon, which by definition is too thin, too dry, too light in color, contains too little organic carbon, has too high an *n* value or melanic index, or is too hard to qualify as any of the other epipedons (Soil

TABLE 33.46 Abbreviated Definitions of Diagnostic Subsurface Horizons in Aridisols

Horizon	Properties
Argillic	Clay accumulation relative to overlying horizon, evidence of clay translocation, minimum thickness of 7.5 cm if loamy or clayey, 15 cm if sandy (Bt)
Calcic	$CaCO_3$ accumulation, generally ≥15 cm thick, ≥15% $CaCO_3$ equivalent, ≥5% more $CaCO_3$ than underlying horizon. In coarse-textured soil > 5% $CaCO_3$ equivalent (Bk or Bkk)
Cambic	Evidence of alteration, reddening, development of soil structure, loss of carbonates (Bw, B, or Bq)
Duripan	Silica-cemented, does not slake in water or acid, evidence of opal accumulation (Bqm)
Gypsic	Gypsum accumulation, ≥15 cm thick, ≥5% gypsum, ≥1% visible secondary gypsum, thickness in centimeter multiplied by % gypsum has product ≥ 150 (By or Byy)
Petrocalcic	$CaCO_3$-cemented, ≥10 cm thick, or ≥1 cm thick if a laminar cap is underlain directly by bedrock, does not slake in water but dissolves in acid, very hard or harder when dry (Bkm or Bkkm)
Petrogypsic	Gypsum-cemented, ≥10 cm thick, ≥5% gypsum and thickness in cm multiplied by % gypsum has product ≥50, roots cannot enter except in vertical fractures that have a horizontal spacing of ≥10 cm (Bym or Byym)
Natric	Properties of argillic horizon, plus columnar or prismatic structure, or degraded blocky structure, sodium adsorption ratio (SAR) ≥ 13 or exchangeable sodium percentage (ESP) ≥ 15 (Btn)
Salic	Accumulation of salts more soluble than gypsum, ≥15 cm thick, electrical conductivity (EC) ≥ 30 dS/m, thickness in centimeter multiplied by EC has product ≥ 900 (Az, Bz, or Cz)

USDA-SCS. U.S. Government Printing Office, Washington, DC, 1975.

Horizon designations typically associated with diagnostic horizons are given in parentheses.

Survey Staff, 1999). Dark anthropic epipedons can also occur in Aridisols, but are very rare and localized. If irrigated for long time periods, a mollic-like epipedon can form, but is grouped with the anthropic epipedons rather than the mollic for taxonomic purposes (Soil Survey Staff, 1999). Surface horizons of Aridisols are uniquely different from surface horizons of more humid soils because of their desert pavement, desert varnish, vesicular A horizon, or biological soil crusts.

33.10.3.2 Subsurface Horizons

Subsurface horizons include the cambic, argillic, natric, calcic, petrocalcic, gypsic, petrogypsic and salic horizons, and the duripan. None of these horizons is unique to Aridisols, although the occurrence of salic, gypsic, and petrogypsic horizons in other soil orders is rare. A summary of the properties of these horizons is given in Table 33.46. Many combinations of these horizons are possible in Aridisols depending on the interaction of the five soil-forming factors. As an example, Figure 33.67 shows a petrocalcic, calcic, and argillic horizons, as well as the ochric epipedon in two Aridisols in the southwestern United States. Despite being in arid climates, Aridisols can have prominent pedogenic horizons that display advanced stages of soil development (cf., Huenneke and Noble, 1996).

33.10.3.3 Suborders, Great Groups, and Subgroups

The nine subsurface horizons (Table 33.46) and the cryic soil temperature regime are used to differentiate seven suborders, presented below in the sequence they are keyed out in *Soil Taxonomy*: (1) Cryids (Aridisols in cold areas), (2) Salids (accumulations of salts more soluble than gypsum), (3) Durids (accumulations of and cementation by secondary silica), (4) Gypsids (accumulations of gypsum), (5) Argids (accumulations of illuvial clay), (6) Calcids

(accumulations of pedogenic carbonates), and (7) Cambids (weak translocation or transformation of subsoil material). The Cryids occur at high latitudes and high elevations and are common in the intermountain western region of the United States (Hipple et al., 1990). The Argids, Durids, and Petrocalcids (petrocalcic horizon) occur on the oldest geomorphic surfaces, usually late Pleistocene and older, as on the least eroded parts of dissected alluvial fans. Cambids and other Calcids are found on geologically younger side slopes and surfaces of intermediate age, usually latest Pleistocene or younger. Gypsids and Salids often occur near playa margins, where salts are concentrated at or near the soil surface by upward flux from a water table. Less commonly, they occur in association with Cambids and Calcids where parent materials are saline or where gypsum is added with eolian material (Reheis, 1987; Eswaran and Gong, 1991).

The keying sequence follows, for the most part, properties that have the greatest constraints to use and management (Ahrens and Eswaran, 2000). The cold climate of Cryids, for example, presents a limitation that cannot be overcome by reclamation efforts. Similarly, the Salids present special problems because drainage and high-quality water are required before productive agriculture is possible. These 7 suborders are subsequently subdivided into 28 great groups, which in turn are subdivided into more than 269 subgroups (Table 33.47). The great groups are differentiated on the basis of a number of other properties, including aquic conditions, cementation of horizons by gypsum or carbonates, and presence of diagnostic subsurface horizons not identified at the suborder level, generally at depths between 100 and 150 cm. Subgroups are differentiated by a large number of properties. Some common criteria are shallow lithic contacts, presence of nodules and concretions, soil properties that grade toward Andisols or Vertisols, and soil moisture regimes that border on ustic and xeric.
FIGURE 33.67 Morphological and micromorphological features of two Aridisols in southern New Mexico. (a) Illustration of a petrocalcic horizon containing (b) authigenic palygorskite fibers radiating into pore space and (c) calcified fungal hyphae filaments (cf.) suggesting biomineralization of calcite by soil microbes. (d) Illustration of the degradation of a calcic horizon indicated by K-fabric crosscut by noncalcareous material (e) and a vertical pipe containing grain argillans suggesting clay illuviation (f).

33.10.4 Properties

33.10.4.1 Physical Properties

Physical properties of Aridisols can vary dramatically within a local landscape as a consequence of differences in the five soil-forming factors. Particle size distribution, for example, in an area $32 \times 32\,km^2$ ($400\,mi^2$) area in southern New Mexico contains soils with nine particle size classes: sandy-skeletal, loamy-skeletal, clayey-skeletal, sandy, coarse-loamy, fine-loamy, fine-silty, fine, and very fine (Gile et al., 2003). In the same area, bulk density values ranges from a high of $2.19\,g\,cm^{-3}$ in the laminar zone of a petrocalcic horizon to a low of $0.99\,g\,cm^{-3}$ in a gravelly loam B horizon. Infiltration is highly variable as well. When a silty soil surface becomes barren upon the loss of desert grasses and becomes sealed via a physical crust, the amount of water entering the soil is significantly reduced compared with neighboring soils still coved with grasses (Herbel and Gibbens, 1989; Bhark and Small, 2003). Consequently, positive feedback loops develop (Ludwig et al., 2005; Monger and Bestelmeyer, 2006) that exacerbate desertification and create heterogeneous vegetative patterns, such as banded vegetation and localized "islands of fertility" (Schlesinger et al., 1990; Tongway et al., 2001; Rango et al., 2006).

33.10.4.2 Chemical Properties

Organic C and nitrogen contents in Aridisols are among the lowest for all soils. Maximum concentration of organic C in ochric epipedons is often <1% on a mass basis due to low biomass production and rapid decomposition. In Aridisols, as in other soil orders, organic C is inversely related to mean annual soil temperature. Thus, in cool and cold arid regions (frigid and cryic soil temperature regimes), organic C contents rival those of warmer semiarid to subhumid climates (Southard, 2000). Nitrogen occurs mostly in organic matter and is quickly nitrified after the organic matter is decomposed. The NO_3^- produced is susceptible to some leaching, but more importantly, to runoff during overland flow and accumulation in playa environments where denitrification can occur (Schlesinger et al., 1990, 2006).

Soluble salts have accumulated in some, but not all, Aridisols as the result of limited leaching and high evaporation near the soil surface. The presence of salts in Aridisol profiles reflects their high solubility and indicates their relative susceptibility

to downward leaching vs. upward movement of groundwater due to evaporation. Typically, well-drained Aridisols have chromatographic-type accumulations of the most soluble salts (chlorides and sulfates) at greater depths than those that are less soluble (gypsum and calcium carbonate), whereas more poorly drained Aridisol have soluble salts closest to the surface. The distribution of these salts within the soil profile is reflected in the electrical conductivity (EC) (Table 33.48; Figure 33.68).

Exchangeable sodium and pH can be uniquely higher in Aridisols than in other soils. The high accumulation of Na on the cation exchange complex is a common phenomenon in Aridisols (exchangeable Na is related to Na in solution and is reflected in the Na adsorption ratio [SAR]) (Table 33.48). Hydrolysis of exchangeable Na, particularly when electrolyte concentrations

are low (i.e., little or no soluble salts), can produce alkaline soil reactions near pH 10. Swelling and dispersion of soil clays can cause plugging of soil pores and reducing permeability (Levy, 2000). Clay dispersion also enhances the mobility of clay particles in the soil solution and increases the accumulation of clay in subsoil horizons, particularly for natric horizons.

33.10.4.3 Mineralogical Properties

Mineral diversity is high in Aridisols compared with other soil orders for several reasons. First, Aridisols are widely distributed throughout a wide range of parent materials over vast areas of Earth's surface (Figure 33.65; Nettleton and Peterson, 1983; Allen, 1990). Second, in young Aridisols, there has been relatively little weathering of inherited minerals since the arid

climate provides little surplus water for mineral hydrolysis or for leaching of weathering products. Third, the dry climate enables soluble minerals to accumulate that would otherwise be flushed from soils of more humid climates. Fourth, older Aridisols span multiple glacial–interglacial cycles of the Pleistocene; thus, the mineralogy of wetter paleoclimates is superimposed on the mineralogy of arid recent climates, such as the kaolinitic soils in regions of West Africa and Australia.

Consequently, family mineralogic classes for Aridisols in *Soil Taxonomy* include the following categories: Mixed, Smectitic, Carbonatic, Gypsic, Siliceous, Glassy, Illitic, and Kaolinitic (Southard, 2000). Mineralogy of the sand and silt fractions generally reflects relatively little weathering with a silicate mineral suite that is dominated by quartz, feldspar, amphiboles, and micas, with a few Aridisols containing abundant inherited zeolites (Allen, 1990; Ming and Boettinger, 2001). Mineralogy of the clay fraction is usually dominated by smectites (usually montmorillonite), as reflected by the family mineralogical classes of *Soil Taxonomy* (Southard, 2000). However, even within a small region, the suite of clay minerals can be diverse. Analysis of 154 horizons from 72 pedons revealed the presence of illite, kaolinite, smectite, palygorskite, sepiolite, chlorite, interstratified mica-montmorillonite, and vermiculite (Monger and Lynn, 1996). In these Aridisols, illite and kaolinite were found to be ubiquitous and their concentrations changed little with depth or age, unlike smectite whose concentration formed a bulge in

B horizons and became more abundant with age. Palygorskite and sepiolite occurred in well-developed petrocalcic horizons, whereas chlorite, interstratified mica-montmorillonite, and vermiculite were more common in soils formed in igneous parent material than in soils derived from limestone.

Mineralogy of Aridisols may have significant contents of relatively soluble, nonsilicate minerals, including calcite ($CaCO_3$), gypsum ($CaSO_4 \cdot 2H_2O$), halite ($NaCl$), thenardite (Na_2SO_4), mirabilite ($Na_2SO_4 \cdot 10H_2O$), epsomite ($MgSO_4 \cdot 7H_2O$), nahcolite ($NaHCO_3$), and trona ($Na_2CO_3 \cdot 10H_2O$) (Doner and Lynn, 1989; Buck et al., 2006).

33.10.5 Pedogenesis of Aridisols

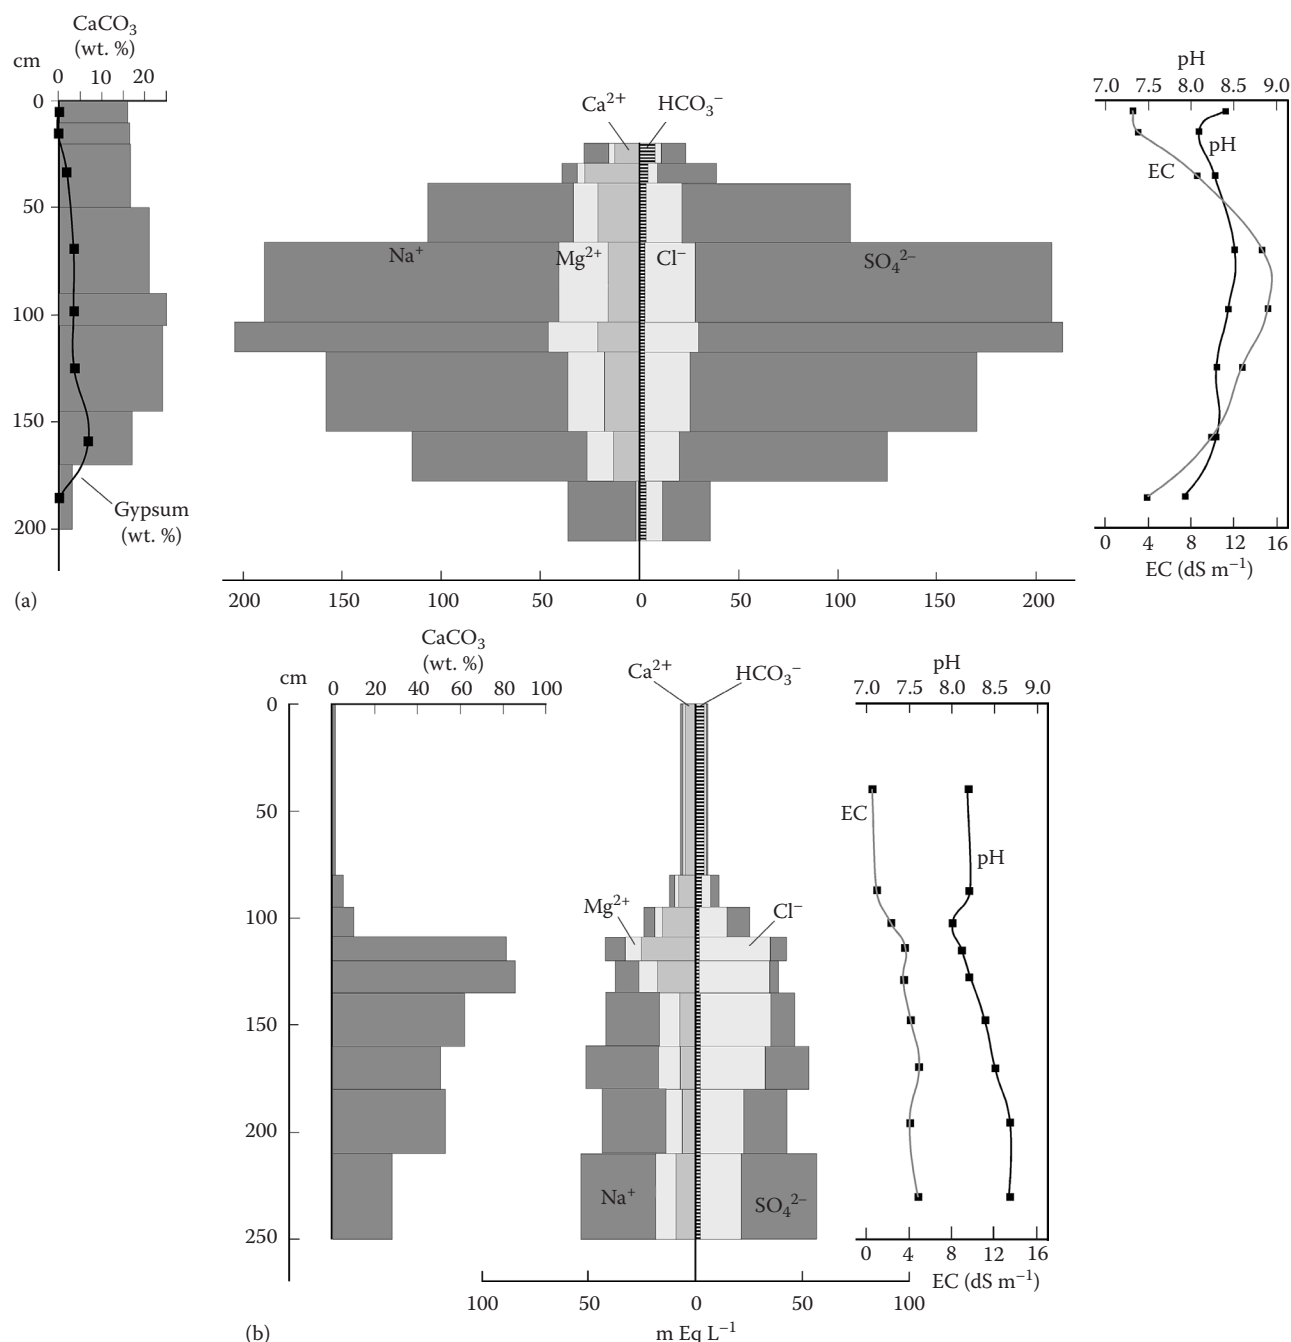
The most distinguishing characteristic about soil formation in Aridisols is the limited water available for plant growth, mineral weathering, and leaching of soluble weathering products. A typical water budget is dominated by a long period of deficit during the summer when potential evapotranspiration greatly exceeds precipitation followed by partial recharge of water-holding capacity, then rapid utilization of that stored water during the brief growing season. The lack of a surplus of precipitation over evapotranspiration and water-holding capacity prevent wholesale leaching of weathering products from Aridisols. Nonetheless, many Aridisols have well-developed soil profiles due to (1) the concentration of the limited


FIGURE 33.68 Salinity profiles, pH, EC, $CaCO_3$, and gypsum content illustrating chemical properties of two Aridisols in southern New Mexico. (a) Vertic Haplocambid formed in the clayey sediments of a playa with high soluble salt concentrations and (b) a neighboring Argic Petrocalcid formed sandy alluvium on a basin floor.

water in a relatively small volume of the upper soil profile, (2) occasional periods of relatively high precipitation in the winter months when deeper leaching could occur, and (3) wetter paleoclimates. The depth of leaching and horizon development may reflect the rainfall of the extreme years, rather than that of average years (Archibold, 1995).

Working in concert with the effects of soil moisture is the effects of soil temperature. Soil temperature regimes of Aridisols range from cryic to isohyperthermic (Soil Survey Staff, 1999).

Although the rate of chemical weathering increases as temperature increases (Buol et al., 2002), Aridisols in cooler temperatures retain water longer and dissolve more CO_2 (Breecker et al., 2009). Most Aridisols develop in sediments transported by wind or water on relatively low gradient landscapes. Lithology of the sediments varies widely. Truncation of steep landforms and slow weathering rates retard the formation of subsurface soil horizons and result in Entisols on most erosional landforms (Nordt et al., Section 33.4). Some Aridisols have formed in residual rock

material on erosional landforms, for example, on old and highly weathered granitic pediments in the Mojave Desert (Boettinger and Southard, 1991, 1995) and on stable, steep hills where episodic erosion has been minimal (Nettleton and Peterson, 1983).

The four generalized soil-forming processes of additions, transformations, translocations, and losses (Simonson, 1959) are operating in Aridisols, as in more humid soils, but at different rates. Of particular importance, as discussed in the sections below, are eolian accretions and rain chemistry (additions), neoformation of silicate clay, silica, carbonate, and gypsum (transformation), and illuviation of silicate clay (translocations).

33.10.5.1 Atmospheric Additions

Because Aridisols that are of the "nonflushing type" (Rode, 1962), their profiles are cumulative repositories of airborne particles and rain-borne cations and anions. These atmospheric additions have major impacts on the physical and chemical properties and provide a historical record of paleoenvironmental changes (e.g., Chadwick and Davis, 1990; Reynolds et al., 2001; Graham et al., 2008).

33.10.5.1.1 Eolian Accretions

Eolian accretions in many Aridisols are well documented (Yaalon and Ganor, 1973; Gile and Grossman, 1979; Reheis, 1987; Reheis et al., 1995; Valentine and Harrington, 2006). The role of eolian dust is particularly important in many Holocene Aridisols, where much of the carbonate, gypsum, and opaline silica are derived from an external source (Harden et al., 1991). In some cases, eolian material constitutes nearly the entire fine-earth fraction and accounts for the nearly stone-free vesicular horizons below many desert pavements (McFadden et al., 1987). Eolian accretion in Aridisols is enhanced if they have a surface structure that can trap dust. For example, landscapes derived from rock types that tend to weather to soils with few surface clasts are less likely to have significant eolian accretion because an effective dust trap is absent (Boettinger and Southard, 1991).

Eolian accretion of carbonate dust is often required for the development of thick petrocalcic horizons in soils formed in noncalcareous parent materials given the limited amount of water necessary for silicate mineral weathering (Gile et al., 1966; Birkeland, 1984). Ruhe (1967), for example, calculated that there was insufficient calcium in rhyolite alluvium to account for the large amount of calcium contained in the calcic and petrocalcic horizons formed in rhyolitic alluvium. Moreover, even if the rhyolitic parent material had contained enough calcium, the rocks were only slightly weathered and therefore seemed probable that the source of calcium was atmospheric, especially since depth to groundwater was over 100 m. Eolian accretion of carbonate dust, however, is not prerequisite to the formation of all petrocalcic and calcic horizons. Aridisols formed on limestone bedrock or in limestone alluvium may have some accumulation of calcareous eolian dust, but its impact in terms of carbonate source may be of lesser importance in these soils (Rabenhorst and Wilding, 1986).

33.10.5.1.2 Rainwater Chemistry

Rainwater typically contains various amounts of Ca^{2+}, Mg^{2+}, K^+, Na^+, SO_4^{2-}, and NO_3^-. An important consequence of this impure rain is that it can be an important source of nutrients for arid ecosystems (Schlesinger, 1997). Another important consequence is that calcium in rain, like calcium in dust, is a potential source of calcium for the formation of petrocalcic horizons. For example, a 10-year analysis of dust trap data revealed that the calcareous dust, combined with water-soluble calcium extracted from the dust, could generate 0.4 g of soil $CaCO_3$ per meter squared per year (Gile and Grossman, 1979). Rain, however, could generate 1.5 g m^{-2} $year^{-1}$, assuming 200 mm of annual rainfall and a Ca^{2+} concentration of 3 mg L^{-1} (Gile et al., 1981).

33.10.5.2 Surface Features

Pedogenic processes in Aridisols produce unique surface features not found in soils of more humid regions (Cooke et al., 1993). Of special interest are (1) desert pavement, (2) desert varnish, (3) vesicular horizons, and (4) biological soil crusts. In each case, the open surface exposure to sun, wind, rain, temperature fluctuations, and lack of vascular plant roots are involved with their formation.

33.10.5.2.1 Desert Pavement and Varnish

Desert pavement, a surficial layer of rock fragments, usually one or two fragments thick, occurs on many Aridisols (Figure 33.69a and b). The origin of desert pavement has been attributed to loss of fine particles by wind deflation, water erosion, splitting of stones, vertical sorting of coarse fragments by repeated wetting and drying, and by rafting of surface fragments by infiltrating eolian material (Springer, 1958; Cooke, 1970; McFadden et al., 1987). In the case of rafting of surface fragments (Figure 33.69b), the pavement itself serves as a dust trap (Yaalon and Ganor, 1973; Gile, 1975a; Peterson, 1977). The clasts shown in Figure 33.69a, for example, act as a dust trap to catch eolian materials derived from nearby playa and alluvial fans. The effectiveness of desert pavement decreases as surface fragments become more interlocked. When the land surface is nearly completely covered by pavement, the surface neither retains much new eolian material nor loses much material to erosion, unless disturbed.

Desert varnish is a yellowish- or reddish-brown to nearly black coating on desert pavement rock fragments. The varnish is commonly black on pebble surfaces aboveground, but reddish-brown, red, or yellowish red belowground in soils with argillic horizons (Gile and Grossman, 1979). Its composition includes 2:1 silicate clay minerals and oxyhydroxides of Fe and Mn. These constituents are probably of eolian origin and appear to be microbially precipitated (Dorn and Oberlander, 1981; Broecker and Liu, 2001). The varnish occurs most frequently on stable, mafic and various other rock fragments and is generally thickest (as much as 100 μm thick) and darkest on Pleistocene pavements (Nettleton and Peterson, 1983; Garvie et al., 2008). Desert varnish can form in little more than a decade and may serve as an armor that protects microbial weathering fronts from harsh
FIGURE 33.69 (a) Desert varnished on clasts interlocking to form a nearly continuous desert pavement on a Pleistocene basalt flows in the Mojave Desert, California. Tape length is about 30 cm. (b) Vesicular surface horizon (an Av horizon) rafting atop desert-varnished basalt pebbles of a desert pavement in the Cima volcanic field in the Mojave Desert. Lens cap is about 60 mm. (c) Diagram of desert pavement underlain by a thin, vesicular A horizon. (From Gile, L.H., and R.B. Grossman. 1979. The desert project soil monograph. USDA-SCS, Washington, DC.) (d) Biological soil crust covering an otherwise bare inter-vegetative surface of a silty soil in the Chihuahuan Desert, New Mexico.

desert environments of irradiation, extreme temperature fluctuations, and low moisture conditions (Krumbein and Jens, 1981). Comparison of desert varnish on exposed stones of adjacent geomorphic surfaces, the same age shows desert varnish to be absent on limestone (Gile and Grossman, 1979), unless the limestone contains exposed deposits of chert or silicified veins.

33.10.5.2.2 *Vesicular A Horizons*

Beneath the pavement, especially in silty eolian material, a horizon may form with many fine, discontinuous vesicular pores. These horizons are widespread feature of Aridisols and are generally referred to as an Av horizon ("v" in this context is not to be confused with "v" used to describe horizons with plinthite) (Figure 33.69c). The vesicles result from repeated saturation and desiccation and progressive enlargement of air bubbles trapped beneath the thin, saturated surface layer (Springer, 1958; Miller, 1971). Av horizons coevolve with the formation of desert pavement (Anderson et al., 2002). The rate at which vesicular A horizons form can be quite rapid based on the observation that well-developed vesicular horizon formed in tire tracks known to be less than 2 years old (Gile and Grossman, 1979). The discontinuous porosity of Av horizons, in addition to their platy structure, leads to low infiltration rates and shallow leaching that affect ecologic function (Turk and Graham, 2009).

33.10.5.2.3 *Biological Soil Crusts*

A continuum of crust types occupies surfaces of many Aridisols depending on climate, soil properties, and disturbance history

(Johnston, 1997; Belnap and Lange, 2001). On one end is the abiotic physical crust; on the other end are mosses. Soil biological crusts (a.k.a., microbiotic or cryptogamic crusts) include the cyanobacterial crusts, green algae crusts, lichen crusts, and mosses. Abiotic physical crusts are widespread, but not present everywhere, and appear as a surficial layer of uncemented, coherent fine earth that can be broken free from underlying soil. The crust is generally less than 10–20 mm thick and is often platy in the upper part and massive below. Water infiltration into physical crust is slow, in contrast to the rapid infiltration into uncrusted coppice sand dunes. Physical crusts form by raindrop impacts, localized sheet erosion, and by repeated wetting and drying of loamy soil material (Nettleton and Peterson, 1983).

Biological soil crusts occupy many habitats. They occur on top of the soil surface, within soil, beneath translucent stones, within rock fissures and cracks, and within the airspaces of porous rocks. Functions of biological soil crusts include stabilizing soil surfaces (Belnap and Gillette, 1998), increasing mineral weathering, fixing nitrogen (Malam Issa et al., 2001; Belnap, 2002), modifying evaporation (Verecchia et al., 1995), decreasing seed germination until periodically disturbed (Prasse and Bornkamm, 2000), influencing populations of other soil microorganisms, such as nematodes (Zhi et al., 2009), and affecting surface hydrology (Belnap, 2006). Biological soil crusts can decrease as well as increase runoff depending on the crust type and soil setting. In some sandy soils, cyanobacterial crusts increases runoff as the result of hydrophobic properties and pore plugging, in contrast to silty soils where the roughness

of lichen crusts slows overland flow and increases infiltration (Kidron et al., 2003; Kidron, 2007).

33.10.5.3 Weathering and Silicate Clay Formation

Physical weathering in Aridisols in the form of disintegration of rock results from many processes, most prominent of which are thermal expansion and contraction, ice crystal growth, root growth in cracks, and salt crystal growth (Birkeland, 1999). Chemical weathering, despite being hampered by long periods of dryness, can be substantial depending on soil age. In Holocene Aridisols of North America chemical weathering is minimal due to the aridity of the Holocene climate (Antevs, 1955). In other regions, such as South Africa, mid-Holocene climates during the Altithermal were wetter and warmer (Linacre and Geerts, 1997). But even in North America, ferrugination (reddening) in arid Holocene soils has been sufficient to create cambic horizons, thus converting Torriorthents into Haplocambids (Gile et al., 1995). Aridisols on Pleistocene landscapes in North America show clear signs of weathering, such as the transformation of primary silicate minerals to Ca- and Mg-rich clays (Harden et al., 1991), interstratified mica-vermiculite (Eghbal and Southard, 1993a), vermiculite and Al-rich smectite (Boettinger and Southard, 1995), and Ca and silica in calcareous duripans (Boettinger and Southard, 1991; Eghbal and Southard, 1993c). In addition, the deeply weathered granitic pediments of the Mojave Desert, alteration of biotite to vermiculite are extensive. These alteration and neosynthesis of Al-rich smectites from feldspar weathering are the main sources of phyllosilicates in the clay fraction (Boettinger and Southard, 1995). Similar evidence of silicate clay neoformation during more humid conditions of the Pleistocene was found in the granitic soils in the Chihuahuan Desert (Monger and Lynn, 1996), as discussed in Section 33.10.4.3.

The pedogenic formation of the fibrous clays, palygorskite [ideal structure: $Si_8Mg_5O_{20} \cdot (OH)_2(OH_2^-)_4 \cdot 4H_2O$], and sepiolite [ideal structure: $Si_{12}Mg_8O_{30}(OH)_4(OH_2)_4 \cdot 8H_2O$] (Singer, 1989) has been documented in the alkaline, Si-preserving environment of petrocalcic horizons. Scanning electron microscopy of palygorskite fibers radiating into pore spaces has been used as evidence of in situ formation, rather than illuviation of palygorskite (Figure 33.67b; Monger and Daugherty, 1991a).

33.10.5.4 Pedogenic Silica

Pedogenic silica in Aridisols accumulates as opal ($SiO_2 \cdot nH_2O$) (Flach et al., 1969; Chadwick et al., 1987a), opal-CT (Monger and Kelly (2002)), and possibly as chalcedony and microcrystalline quartz (Flach et al., 1973; Smale, 1973; Milnes et al., 1991). Incipient cementation produces horizons that are very hard when dry and brittle when moist. More complete cementation of the soil by opal produces a duripan. Pedogenic silica, as with pedogenic carbonate, has stages whereby progressively more complex silica accumulations occur on progressively older geomorphic surfaces (Taylor, 1986). But unlike pedogenic carbonate, which cements by engulfing soil particles like mortar between bricks, pedogenic silica cements by bonding soil particles at contacts like glue (Chadwick and Nettleton, 1990). Relatively small amounts of silica (about 10% by weight) cause significant cementation of clay particles (Nettleton and Peterson, 1983), which can significantly change water retention characteristics and CEC. Cementation by silica tends to be less disruptive of soil fabric than cementation by carbonate.

Climate is an important factor for the accumulation of pedogenic silica. It must provide enough water for weathering, but not enough for intensive leaching (Flach et al., 1973). This condition is met in many arid and semiarid climates. The second condition is a readily available source of $H_4SiO_4°$. This condition is met in many areas where easily weatherable volcanic ash and ultramafic materials rapidly release $H_4SiO_4°$ (Alexander et al., 1994; Alexander, 1995).

Secondary silica in the form of opaline veins and stringers is a frequent feature in many highly indurated petrocalcic horizons (Franks and Swineford, 1959). The source of this silica may be derived by weathering of siliceous rocks (Boettinger and Southard, 1991), volcanic ash (Chadwick et al., 1987b), or eolian dust (Harden et al., 1991). It may also originate from the replacement of quartz and feldspar grains by pedogenic calcite. As revealed by thin section petrography, the original shapes of some silicate grains are gone, occupied instead by calcite—hence, the term "replaced" (Swineford et al., 1958; Reheis, 1988; Monger and Daugherty, 1991b). Replacement of silicate grains has been attributed to *force-of-crystallization* (Maliva and Siever, 1988a, 1988b). This process, like pressure solution in metamorphic rocks, is based on the principle that minerals are more soluble at contact points when under stress. The force-of-crystallization hypothesis in petrocalcic horizons is postulated to occur as calcite progressively crystallizes and engulfs detrital grains. It accounts for why some surface pits in silicate grains match the shapes of calcite crystals impacted against them, and it eliminates the need to have unverifiable high pH to account for silica dissolution (Maliva and Siever, 1988b). Silica released by force-of-crystallization would not only precipitate as opaline phases, but would also be a source of Si for authigenic palygorskite and sepiolite, which are common clay minerals in petrocalcic horizons (Vanden Heuvel, 1966; Monger and Daugherty, 1991a; Reheis et al., 1992).

33.10.5.4.1 Duripans and Silcretes

Most duripans in Aridisols have a considerable content of $CaCO_3$, as much as 70% by weight (Southard et al., 1990), but at least half the volume of a duripan does not slake in acid, as petrocalcic horizons do. Many of these duripans have indurated laminar layers as much as 2 cm thick that overlie massive and less strongly cemented material that is highly calcareous. These duripans can be distinguished from petrocalcic horizons only by acid treatment. In many cases, only the upper laminar layer survives the acid treatment intact.

Duripans in Aridisols commonly occur beneath or within an argillic horizon (Flach et al., 1973). In soils with both an argillic horizon and underlying calcic horizon, duripans often straddle the two horizons, superimposed on the lower portion of the argillic and the upper portion of the calcic, thus, forming

a chromatographic column of illuviated constituents (Chadwick et al., 1987a). Silica in duripans is typically some form of opal or chalcedony that is finely distributed throughout the matrix, or as coatings, diffuse isotropic flocs, nodules, glaebules, and stringers (Flach et al., 1973; Boettinger and Southard, 1990; Monger and Adams, 1996). High pH promotes duripan formation in granitic terrain and, in some cases, precludes the requirement for volcanic ash as a source of silica (Boettinger and Southard, 1990).

Silcretes or duricrust in Aridisols is more indurated and generally older than duripans (Jackson, 1957). Their occurrence in the stratigraphic record may stretch back to the Precambrian (Summerfield, 1983). Silcretes develop when sediments become silicified in areas (1) where drainage of silica-rich groundwater is poor and has a fluctuating water table, (2) where silica-rich solutions evaporate, and (3) where upward moving silica-rich solutions meet downward percolating less alkaline or more salty waters (Smale, 1973; Summerfield, 1983; Milnes et al., 1991). Mineralogically, silcretes are a combination of opal-A, opal-CT, and microcrystalline quartz (microquartz) depending on the concentration of $H_4SiO_4°$ (Milnes et al., 1991). Like duripans, high $H_4SiO_4°$ concentrations ($>60\,mg\,L^{-1}$) favor opal-A; intermediate concentrations ($20–60\,mg\,L^{-1}$) favor opal-CT; and low $H_4SiO_4°$ concentrations ($<20\,mg\,L^{-1}$) favor microquartz (Chadwick et al., 1987b).

33.10.5.4.2 Biogenic Silica

Silica cycling by plants, especially grasses, is an important component of Aridisols. Desert plants, especially grasses, use silica for structural stability, mineral nutrition, and antiherbivore defense mechanisms (Iler, 1979; Massey et al., 2006). When silica-containing plants die and decompose, they release silica into the soil as phytoliths. Phytoliths are ubiquitous constituent of not only Aridisols, but most soils (Wilding et al., 1977; Meunier et al., 1999), ranging from 8 to $300\,kg\,ha^{-1}$ depending on biomass production and mean annual precipitation (Pease, 1967; Kelly, 1989). Except for certain silica-rich geological environments, such as hot springs, most soil opal has a biogenic origin that exerts a major control on silica in the soil solution (Alexandre et al., 1997). The marine record indicates that biogenic silica underwent a spectacular expansion during the middle Cenozoic when grasses proliferated across terrestrial environments (Lowenstam and Weiner, 1989). Vertically in soils, phytoliths are most abundant in surface horizons and decreases with depth, unless buried paleosols are encountered. In paleosols, phytolith morphology and isotopic composition can be a useful method for providing information about ecological and archaeological changes (Wilding and Drees, 1974; Kelly et al., 1991; Rosen and Weiner, 1994; Schaetzl and Anderson, 2005).

33.10.5.5 Pedogenic Carbonate

Several names have been given to pedogenic carbonate: caliche, calcrete, croute calcaire, tosca, caprock, crust, calcic horizons, and petrocalcic horizons (Gile, 1961; Goudie, 1973; Dregne, 1976; Soil Survey Staff, 1999). Although some pedgenic carbonate has been reported to be dolomite (e.g., Capo et al., 2000), the vast majority is calcite (e.g., Doner and Lynn, 1989; Kraimer et al.,

2005). Pedogenic carbonate is a subset of *soil carbonate*, which is the total amount of carbonate measured in the soil, typically by acid dissolution methods, and reported as calcium carbonate equivalent (Soil Survey Staff, 1996). Soil carbonate is a broad category containing *primary carbonate* (if present) and *pedogenic carbonate* (if present). Primary carbonate (also termed geogenic, lithogenic, inherited, or nonpedogenic) is $CaCO_3$ originally precipitated in aquatic environments as limestone. Pedogenic carbonate (also termed secondary or authigenic carbonate) is $CaCO_3$ developed in soil and can occur as either authigenic (in situ) $CaCO_3$ or allogenic (ex situ) $CaCO_3$, where allogenic $CaCO_3$ is derived from preexisting soils upslope or downwind. The age of pedogenic carbonate spans vast time periods, ranging from carbonates in Paleozoic paleosols (Mora et al., 1996) to carbonate formed on artifacts (Pustovoytov, 2002) and living plant roots (Monger et al., 2009).

Of the global amount of soil carbonate, Aridisols contain the largest proportion (48%), followed by Entisols (28%), and Mollisols (12%) (Eswaran et al., 2000). At the suborder level, however, Orthents contain the most (21.4%) because many Orthents are formed by the truncation of Aridisols (see Nordt et al., Section 33.4). Other suborders containing notable amounts of soil carbonates are Calcids (17.4%), Argids (14.2%), Cambids (10.0%), Ustolls (9.9%), Psamments (3.5%), Ustalfs (3.1%), Fluvents (2.8%), Gypsids (2.4%), and Salids (2.2%) (Eswaran et al., 2000).

Calcium carbonate is present in almost all Aridisols, except for some Aridisols on stable platforms in West Africa and Australia (Southard, 2000). Inputs of Ca from mineral weathering or from the atmosphere, either dissolved in rainwater or as particles of Ca-bearing minerals, coupled with relatively low solubility, cause $CaCO_3$ to accumulate. Once in soil solution, Ca can react with HCO_3^- from rainwater or produced via soil CO_2 (from respiration) with water. Loss of water by evaporation, or reduction of the partial pressure of CO_2 (P_{CO_2}), drives the precipitation of $CaCO_3$ from solution.

Aridisols on Holocene or latest Pleistocene landscapes in the southwestern United States, for example, are often calcareous in all horizons because the relatively dry conditions of the Holocene prevented leaching of carbonate from surface horizons (e.g., Typic Haplodurid and Typic Calcigypsid in Table 33.48). In contrast, Aridisols on older Pleistocene landscapes are often carbonate free in the upper horizons, presumably due to more effective leaching during the cooler, moister Pleistocene (e.g., Typic Haplargid and Argic Petrocalcid in Table 33.48). Aridisols of West Africa are acidic and lack carbonates because they form on old preweathered platform surfaces or from more recent polycycled sediments derived therefrom.

Soil taxonomy systems have used pedogenic carbonate as an important feature to classify soils (e.g., Pedocal vs. Pedalfer, Marbut, 1928). Pedogenic carbonate has also provided important clues about paleoclimate, paleoecology, paleoatmospheric composition, relative ages of geomorphic surfaces, landscape evolution, carbon sequestration, and vegetation patterns in arid landscapes (e.g., Mora et al., 1996; Ekart et al., 1999; Monger and Martinez-Rios, 2001; Duniway et al., 2007).

33.10.5.5.1 *Pedogenic Carbonate Forms*

Forms of pedogenic carbonate accumulation have been described as filamentary, concretionary, cylindroidal, nodular, platy, blocky, bedded, massive, veined, and flaky, as well as root casts, bands, joint fillings, coatings, pendants, beds, plugged horizons, laminar horizons, laminae, pisoliths, and ooliths (Gile, 1961; Harden et al., 1991; Eghbal and Southard, 1993b; Soil Survey Division Staff, 1993). These carbonate forms range from nonindurated, which slake when placed in water, to very strongly indurated, which do not slake in water and cannot be scored with a knife. On the low end of carbonate accumulation, horizons with carbonate filaments can contain as little as 1% $CaCO_3$ and, depending on texture, have typical bulk densities (e.g., 1.68 g cm^{-3}) and high infiltration rates (e.g., 12.4 cm h^{-1}, Gile, 1961). On the high end of carbonate accumulation, laminar horizons can contain over 90% $CaCO_3$ with high bulk densities (e.g., 2.22 g cm^{-3}) and low infiltration rates (e.g., 0.1 cm h^{-1}).

Pedogenic carbonate is an important indicator of soil age because progressively older geomorphic surfaces contain progressively greater amounts of carbonate. It was observed that with time, four morphogenetic stages of carbonate develop, progressing from having no visible carbonate to having stage I filaments, then stage II nodules, a stage III plugged horizon, and eventually a stage IV laminar horizon developed atop the plugged horizon (Gile et al., 1966; Figure 33.70). More recently, two additional stages of carbonate accumulation have been added: stages V and VI (Machette, 1985). Stage V contains thick laminae (>1 cm) and pisolites, and stage VI contains multiple generations of laminae, breccia, and pisolites. The time required to reach a certain morphogenetic stage depends on soil texture. Gravelly soils pass through the stages more quickly than fine-textured soils because gravelly soils have lower surface area and less pore space. Associated with an increase in pedogenic carbonate is a large expansion of the volume of the calcic and petrocalcic horizons as carbonate precipitates and forces matrix grains apart. Cementation of horizons occurs when carbonate content reaches 25%–60% (Machette, 1985).

Until about 1965, horizons with carbonate accumulation were designated as C horizons with a "ca" suffix (or "cam" suffix if indurated) following the procedure of the *Soil Survey Manual* (Soil Survey Division Staff, 1951). Subsequent work showed that carbonate accumulation was a pedogenic process (Gile et al., 1965). Therefore, horizons with significant amounts of pedogenic carbonate were afterward designated B horizons,

Schematic diagram of diagnostic carbonate morphology for the stages of carbonate accumulation in the two morphogenetic sequences (left below). Stages are described (right below), including stages V and VI not shown in diagram

Carbonate morphogenetic stages   Definitions of carbonate morphogenetic stages

	Diagnostic carbonate morphology	
Stage	Gravelly sequence[a]	Nongravelly sequence
I	Thin pebble coatings, continuous in last part of stage.	Few[b] filaments, masses, or faint coatings
II	Continuous pebble coatings, some interpebble masses.	Few to common nodules or masses.
III	Many interpebble masses; plugged horizon[c] develops in last part of stage.	Many nodules and internodular masses; plugged horizon develops in last part of stage.
IV	Laminar horizon overlying plugged horizon.	Laminar horizon overlying plugged horizon.
V	Very strongly cemented to indurated with >1 cm thick laminae; may contain pisoliths and have vertical faces and fractures coated with laminated carbonate.	
VI	Indurated with multiple generations of recemented laminae, breccia, and pisoliths.	

[a] Morphologies are best expressed where "nongravelly" materials contain less than about 20% by volume of rock fragments (fragments 2 mm or larger in diameter), and "gravelly" materials contain more than about 60% by volume of rock fragments. Materials that have between 20% and 60% by volume of rock fragments have intermediate morphologies.

[b] Few <2, common 2 to <20, many = 20 or greater percent of area covered.

[c] Plugged horizon contains 50% or more pedogenic carbonate (by vol).

FIGURE 33.70 Illustration and definitions of the morphogenetic stages of pedogenic carbonate accumulation in gravelly soils and soils without gravels. Stages V and VI are not shown in diagram. (From Gile, L.H., F.F. Peterson, and R.B. Grossman. 1966. Morphological and genetic sequences of carbonate accumulation in desert soils. Soil Sci. 101:347–360; Machette, M.N. 1985. Calcic soils of the southwestern United States, p. 1–21. *In* D.L. Weide (ed.) Soils and Quaternary geology of the southwestern United States. Geological Society of America. Special Paper 203.)

not C horizons. The prominence of carbonate horizons in arid and semiarid regions led to the proposed K horizon as a master horizon, such as the O, A, B, C, and R horizons at that time. The K horizon was based on the presence of K-fabric, which is defined as "fine-grained authigenic carbonate that coats or engulfs skeletal pebbles, sand, and silt grains as an essentially continuous medium" (Gile et al., 1965). The K horizon, by definition, contained 90% or more K-fabric. The K horizon was not adopted by the National Cooperative Soil Survey, except that the suffix "k" eventually replaced the "ca" suffix. In other earth science disciplines, however, the K horizon has been used (e.g., Machette, 1985; Birkeland, 1999). Recently, the "kk" suffix, which corresponds to the stage III plugged horizon or higher of the carbonate morphogenetic stages, has been formally adopted by the National Cooperative Soil Survey (Soil Survey Staff, 2010).

33.10.5.5.2 Origin of Pedogenic Carbonate

Models of pedogenic carbonate formation can broadly be classified into four groups (Monger and Wilding, 2002): (1) the *per ascensum*-groundwater model in which carbonate develops from upward rising groundwater via capillarity, (2) the *per descensum*-leaching model in which pedogenic carbonate develops from downward redistribution of calcareous parent material, (3) the *per descensum*-dust model in which pedogenic carbonate develops from atmospheric additions of dust and calcium in rainwater, and (4) the in situ-biogeochemical model in which carbonates develops from biological weathering, Ca upward translocation by hyphae and roots, and precipitation of carbonates within the soil profile via both inorganic and biogenic precipitation. The formation of pedogenic carbonate in any particular soil may involve several of these models working together at different magnitudes.

The *per ascensum*-groundwater model accounts for pedogenic carbonate formation as the result of precipitation of carbonate minerals from groundwater containing high concentrations of Ca^{2+} and HCO_3^- drawn up from shallow water tables by capillarity (Sobecki and Wilding, 1983). This model includes groundwater calcretes. These differ from pedogenic calcretes, that is petrocalcic horizons, in two ways. The groundwater calcretes have coarse (often poikilotopic) interlocking carbonate crystals that engulf detrital grains in contrast to pedogenic calcretes that have fine silt-size carbonate crystals. Second, groundwater calcretes impregnate sediments in a manner that preserves the original sedimentary structure in contrast to pedogenic calcretes that obliterates sedimentary structure.

The *per descensum*-leaching model accounts for pedogenic carbonate formation as the result of dissolution of indigenous carbonates from upper horizons, downward transport of ions in solution, and precipitation of secondary carbonates from soil solution in lower horizons. Biogenic CO_2 raises P_{CO_2} to levels as high as 1.2%, and the relative rates of CO_2 production and loss to the atmosphere by diffusion generally cause P_{CO_2} to increase with soil depth (McFadden et al., 1991). Plant roots take up water preferentially over dissolved HCO_3^-, causing $CaCO_3$ to precipitate due to desiccation. This process occurs in the upper profile

of many calcareous loess and alluvial deposits and was invoked to explain the correlation of progressively shallower carbonate horizons in progressively drier climates (Jenny and Leonard, 1934). Later, this model was used as the basis for calculating the number of wetting fronts required to leach carbonates to a particular depth (Arkley, 1963). In both cases, it was assumed that carbonate was uniformly distributed in parent material at the beginning of pedogenesis.

The *per descensum*-dust model was developed in recognition that pedogenic carbonate also occurs in soils that do not have indigenous calcareous parent materials. In southern New Mexico, for example, prominent calcic and petrocalcic horizons occur in soils with siliceous and only-slightly weathered parent materials. In this case, atmospheric additions were judged to be the source of pedogenic carbonates (Gile et al., 1966). Initially, calcareous dust was considered to be the source. Later, it was recognized that Ca^{2+} in rain was an additional, and even larger, source of Ca^{2+} for reaction with soil HCO_3^- to form pedogenic carbonates (Section 33.10.5.1.2). The depth and rate of $CaCO_3$ accumulation in many Aridisols illustrate the importance of varying eolian input and P_{CO_2} (McFadden et al., 1991). Building on these *per descensum* concepts, compartmental models have been constructed that compute the depth, amount, and distribution of pedogenic carbonate as a function of climate and time (Arkley, 1963; McFadden and Tinsley, 1985; Hirmas et al., 2009; Section 33.10.6).

The in situ-biogeochemical model focuses on the biogenic activity of plants and microorganisms in harvesting Ca from parent material and transporting it to the land surface. This process occurs in all soils, but its effect is more apparent in arid and semiarid soils because of their nonflushing nature and nonacidic pH. The in situ-biogeochemical model operates in both noncalcareous and calcareous parent materials. In noncalcareous parent materials, evidence that various plants play a role in carbonate formation comes from chemical analysis of soil profiles showing that plants transfer Ca^{2+} to the land surface from subsoil, rock, or groundwater (Goudie, 1973). Depending on the chemical environment, a portion of this Ca^{2+} is available for precipitation with HCO_3^- derived from CO_2 generated by root and microbial respiration. Moreover, references in the Russian literature note carbonate formation in plant tissue followed by its downward translocation with wetting fronts (Labova, 1967). Evidence that microorganisms precipitate carbonates is based on microscopy of calcified fungal hyphae (West et al., 1988) and in vitro laboratory experiments (e.g., Philips et al., 1987; Monger et al., 1991). Termites may also precipitate carbonate in large termite mounds of Africa and southeast Asia (Thorp, 1949), but not in small sheaths common in North American deserts (Liu et al., 2007). In formed on limestone bedrock, pedogenic carbonate forms via the progressive transformation of limestone into micritic pedogenic carbonate as a result of short-range carbonate dissolution and reprecipitation processes (Rabenhorst and Wilding, 1986), which is a unique process of pedogenic carbonate accumulation because the content of pedogenic carbonate is less than the carbonate content of the original limestone.

33.10.5.6 Pedogenic Gypsum and Soluble Salts

Soils containing gypsum ($CaSO_4 \cdot 2H_2O$) in the form of gypsic or petrogypsic horizons are estimated to cover some 207 million ha around the world (Eswaran and Zi-Tong, 1991). These soils can be grouped into two categories: *gypsiferous*(in which the suffix-ferous means "yielding" or "containing") or *gypseous* (in which the suffix-ous means "abounding in" or "consisting of"; Herrero and Porta, 2000). Unlike pedogenic carbonates that can form in any soil given a source of free calcium, bicarbonate, and nonacidic pH, gypsum formation is restricted to a parent material source of gypsum.

Soils with gypsum have unique properties because of gypsum's softness (2 on the Mohs scale), its solubility (2.6 g L^{-1} at 25°C), and its ability to corrode iron and disintegrate concrete. The disintegration of concrete occurs when sulfate reacts with Na to form mirabilite or thenardite or with Ca and Al to form ettringite $[Ca_6Al_2(SO_4)_3(OH)_{12} \cdot 26H_2O)]$ and thaumasite $[Ca_3Si(CO_3)(SO_4)(OH)_6 \cdot 12(H_2O)]$ (Herrero et al., 2009). Crystallization of these sulfate minerals increases the volume of solids, thus leading to disintegration.

Gypseous and gypsiferous soils are not necessarily salt-affected soils because gypsum does not significantly increase osmotic potential or ionic toxicity. In fact, gypsum has long been used as a source of calcium and sulfur nutrients, and a material used to reclaim sodic soils (Shainberg et al., 1989). Native vegetation on gypseous soils is distinguished from vegetation of saline soils by having more abundant biomass and greater number species. However, gypseous and gypsiferous can also be saline (Herrero et al., 2009). Salts more soluble than gypsum (soluble salts) most commonly accumulate in soils where there is a source of easily dissolvable minerals or ions in parent material (Gumuzzio et al., 1982), a source of saline water, and a climate with relatively high evapotranspiration rates. Pedogenic accumulation of soluble salts is often associated with gypsum and/or carbonates, depending on the initial ionic composition of the evaporating solution (Boettinger and Richardson, 2001).

Gypsic and salic horizons are typical of basins with playas (Driessen and Schoorl, 1973) where leaching is limited, water tables are high, and where eolian salts are recycled between playas and surrounding terrain. These salts in soil profiles are often seasonally dynamic due to their high solubility and the ease with which they are moved downward by leaching during the wet season and upward by evapotranspiration during the dry season (Eghbal et al., 1989). Aridisols with salic and gypsic horizons may also occur where there is throughflow and seeps (e.g., Buck et al., 2006) and artesian springs in arid to semiarid climates (Boettinger and Richardson, 2001).

33.10.5.7 Illuvial Clay and the Argillic Horizon in Aridisols

The processes by which clay accumulates in Aridisols are similar to those in other soil orders and include disaggregation, dispersion, and illuviation of clays in eolian dust, in situ weathering of primary minerals, illuviation of dispersed clay from surface horizons, and neosynthesis of clay minerals from soil solution (Nikiforoff, 1937; Brown and Drosdoff, 1940; Agriculture Experiment Station-Soil Conservation Service, 1964). Argillic and natric horizons in Aridisols can range in texture from sand to clay with thickness from 7.5 to 75 cm. Argillic and natric horizons generally begin at shallow depths (4–25 cm below the soil surface), which are shallower than argillic and natric horizons in soils of more humid regions. Argillic horizons typically are just above or extend into calcic horizons.

Mineral weathering that produced clays susceptible to dispersion and translocation is primarily a relict of wetter Pleistocene climatic conditions (Nettleton and Peterson, 1983). Wetter conditions of the Pleistocene pluvials were probably also required to dissolve and leach carbonates from surface horizons, the removal of Ca being a prerequisite for dispersion and translocation of the clays (Goss et al., 1973; Southard, 2000). This was shown by the absence of argillic horizons in Aridisols with abundant fragments of limestone in contrast to neighboring Aridisols of the same age formed in igneous alluvium (Gile and Hawley, 1972). The explanation apparently lies in the flocculating effect that carbonates have on clay movement, although clay illuviation has been reported in some calcareous soils (Goss et al., 1973; Pal et al., 2003). The absence of argillic horizons in many Aridisols can be the result of obliteration by landscape dissection (Nordt et al., Section 33.4), engulfment by carbonate (Gile et al., 1969), or faunal mixing (Gile, 1975a,b).

Many argillic horizons in Aridisols appear to be illuvial, even though they lack clay skins (argillans) on peds. This conclusion has been based on several lines of evidence: (1) Soils have thin, grayish E-like horizon with less clay than the underlying reddish-brown or red B horizon; (2) the argillic horizons when traced laterally have prominent clay skins in pipes that penetrate calcic horizon (Figure 33.67f); (3) reddish coatings of silicate clay occur on and in cracks in the tops of petrocalcic horizons and bedrock that underlie argillic horizons without clay skins at shallow depths; and (4) distinct linear bodies of oriented clay occur within peds, interpreted as former clay skins (Buol and Yesilsoy, 1964; Gile and Grossman, 1968; Smith and Buol, 1968; Nettleton et al., 1969, 1975; Gile et al., 1981).

33.10.6 Links to Past Climates

Aridisols are some of the oldest, if not the oldest soils in the world. They range from Cretaceous age or older in Australia (Pillans, 2005), through the Miocene (Hawley, 2005), the Pliocene (e.g., Gardner 1972; Mack et al., 1996), and early Pleistocene in many regions of the world (e.g., Nettleton and Peterson, 1983; Machette, 1985; Alsharhan et al., 1998; Kapur et al., 2000; Matmon et al., 2009). Such ancient soils bear the marks of many paleoclimatic changes at both the landscape scale and profile scale.

At the landscape scale, periods of landscape stability (soil formation) alternate with periods of landscape instability (i.e., erosion and sedimentation), as described by Ruhe (1962):

> By analogy with present condition … and on a theoretical basis … Past pluvial environments in present arid regions, correlative of glacial episodes elsewhere, should have resulted in greater vegetative cover on relatively stable landscapes … and soil formation. Interpluvial environments, as at present, should have resulted in increased aridity, lesser vegetative cover, unstable landscapes subject to severe erosion and to sediment transport.

Because shrublands have much bare ground, erosion increases. In contrast, during wetter climates, grasslands and woodlands (which have little bare ground) increase causing erosion to decrease (Langbein and Schumm, 1958). Such cycles commonly produce stacked sequences of buried paleosols in intermontane basins. Along floodplains, glacial–interglacial climate cycles commonly produce stepped sequences of geomorphic surfaces (Figure 33.71a). In the American Southwest, the model is a follows: (1) Rivers downcut during glacial periods when greater precipitation gives rise to more water in river channels and denser vegetative cover across landscapes, (2) during waning glacial and early interglacial times, river valleys backfill (partially) as a result of less water in the river channels and greater amounts of sediment supplied by erosion from sparsely vegetated landscapes, and (3) aggradation ceases and base levels stabilize during interglacial times, until the cycle began again when downcutting is renewed by the waxing phase of the next glacial cycle (Hawley et al., 1976).

At the pedon scale, mineralogy is a function of climate. Highly weathered minerals can be relics from a wetter climate
(a)
(b)

FIGURE 33.71 (a) Aridisols and Entisols (Torriorthents) on stepped geomorphic surfaces bordering a river flood plain (Torrifluvents) in Sonora, Mexico. The stepped surfaces record climate-controlled entrenchment and partial backfilling. Older land surfaces are topographically higher and can persist for hundreds of thousands of years, especially if armored by petrocalcic horizons. (b) Landscape relationships of different types of Aridisols in the Basin and Range Province, western United States. (Modified from Peterson, F.F. 1980. Holocene desert soil formation under sodium salt influence in a playa-margin environment. Quat. Res. 13:172–186.)

(Section 33.10.4.3). In contrast, soluble minerals reflect dry climates. Pedogenic carbonate is particularly valuable for providing evidence of climate change in at least three forms: its presence or absence, its depth, and its carbon and oxygen isotopes signatures.

Pedogenic carbonate is a feature of aridity (Mack, 1992; Guo et al., 2006). Although it can exist in humid climates under certain circumstances of high water tables and calcareous parent materials (Sobecki and Wilding, 1983), an analysis of 1168 soil profiles with carbonate showed that 95% existed in climates where the annual precipitation is less than 760 mm (Royer, 1999). A typical value of 500 mm (20 in.) has been used as the general boundary between soils with carbonate and soils without carbonate (Birkeland, 1999). The inference, therefore, can be made that paleosols containing pedogenic carbonate formed in dry climates.

Depth of pedogenic carbonate is commonly, but not always, proportional to annual rainfall. In general, greater precipitation corresponds to greater depths carbonate horizons (Jenny and Leonard, 1934; Arkley, 1963; Gile, 1975c). However, erosion, runoff, and run-on can confound this general relationship, as does the seasonal distribution of precipitation. Arid climates with winter rainfall often produce deeper leaching of carbonates than those with a similar amount of summer rainfall (Yaalon, 1983). It has been shown using the USDA-NRCS database that no statistically significant correlation exists between carbonate depth and rainfall, especially for shallow carbonate in arid and semiarid climates (Royer, 1999). Still, within a local region where erosion, runoff, and run-on can be held constant, carbonate depth is likely to be deeper in wetter environments than in drier environments.

Deeper wetting fronts in the Pleistocene are probably responsible for vertical, karst-like pipes that cross-cut petrocalcic and calcic horizons (Figure 33.67d). Similarly, carbonate filaments in B horizons overlying petrocalcic and calcic horizons in soils of Pleistocene age are probably the result of an upward shift in the depth of wetting during subsequent drier climates based on depths of carbonates in soils of Holocene age and radiocarbon dates of the carbonate crystals themselves (Gile et al., 1981; Monger, 2003). Other evidence for climatically driven shifts in carbonate depth includes engulfment of argillic horizons by calcic horizons as the depth of wetting shifts upward with increasing aridity (Nettleton and Peterson, 1983), and micromorphologic evidence of episodic deposition of carbonates, opal, and clay in argillic horizons and duripans (Eghbal and Southard, 1993c).

Simulation models are also useful for understanding links between carbonate depth and climate. Such models have a vertical sequence of compartments, each with a specified texture, bulk density, water-holding capacity, mineralogy, CO_2 content, ionic strength, and temperature (McFadden and Tinsley, 1985). Similarly, models by Marion et al. (1985) and later models by Marion and Schlesinger (1994) and Hirmas et al. (2009) have used stochastic precipitation, evapotranspiration, chemical thermodynamics, soil parameterization, and soil water movement to simulate carbonate distribution. The depth of carbonate for a soil in New Mexico, for example, was modeled as being about 15 cm deeper during wetter Pleistocene climates than its present arid conditions (Marion et al., 1985).

Carbon ($^{13}C/^{12}C$) and oxygen ($^{18}O/^{16}O$) isotopes in pedogenic carbonate contain information about paleoclimate in two ways: paleoecological and paleotemperature. First, $^{13}C/^{12}C$ ratios are linked to the relative abundance of C_4 to C_3 plants (i.e., plants that use either the C_4 or C_3 photosynthetic pathways; Cerling, 1984; Amundson et al., 1988; Ehleringer, 1988; Quade et al., 1989; Monger et al., 2009). Aridisols are associated with both groups: C_4 plants are warm-season desert grasses (although one shrub type is included, *Atriplex* spp.) and C_3 plants are desert shrub species (Sage et al., 1999). Pedogenic carbonate formed in a pure C_3 ecosystem has $\delta^{13}C$ values of around −12‰ to −9‰, in contrast to pedogenic carbonate formed under pure C_4 vegetation which has $\delta^{13}C$ values of around 1‰–3‰ (Cerling, 1999). Aridisols are also associated with a third group—the CAM plants (crassulacean acid metabolism)—which include the cacti and have isotopic values intermediate between C_4 and C_3 plants.

Second, oxygen isotopes have been used to make inferences about paleotemperatures and rainwater sources (Amundson et al., 1996; Liu et al., 1996). With higher mean annual temperatures, rainwater becomes preferentially enriched in ^{18}O, which is preserved in pedogenic $CaC^{18}O_3$ (e.g., Cerling and Quade, 1993). The isotopic signature of rain, however, is complicated because it is influenced by several factors: (1) latitudinal location (isotopically lighter rain occurs poleward); (2) seasonality (winter rain is isotopically lighter and percolates deep in soil); (3) mountain ranges and distance from the coast (isotopically lighter rain at higher altitudes and greater distance from coast); (4) the amount of rain (rain becomes lighter as the amount of rain increases, this includes both monthly rainfall and individual rainfall events); and (5) storm trajectories (source area, including vapor from land, yields different $\delta^{18}O$ values; Grootes, 1993).

33.10.7 Agriculture

Agricultural use of Aridisols is limited chiefly by the lack of irrigation water. Center pivot irrigation, however, has brought vast areas of Aridisols on upland landforms into agricultural production (e.g., Navajo Indian and Saudi Arabia irrigation projects). Where irrigation systems have been developed, most Aridisols present some problems and generally are less well suited for irrigation than are Entisols, such as Torriorthents and Torrifluvents, which are commonly associated with Aridisols (Figure 33.71a). Land leveling to allow flood, furrow, or sprinkler irrigation often exposes duripans, calcic, petrocalcic, natric, or argillic horizons.

Under irrigation, control of salinity in the rooting zone is critical to the long-term success of any crop management system. Flushing of salts by an amount of water in excess of the crop evapotranspiration demand (a leaching fraction) helps reduce salinity in the root zone. The excess water and dissolved salts must be removed by subsurface drainage. The presence of shallow subsurface horizons with slow permeability (duripans, natric or petrocalcic horizons) compounds the irrigation and drainage management problems for crop production, as well as for septic tank leach fields and

irrigation of lawns in urbanized areas. Soil subsidence, due to solution of gypsum, and corrosion of concrete are common problems where soils containing gypsum are irrigated (Nettleton et al., 1982; Section 33.10.5.6). Other than N, most major plant nutrients are abundant in Aridisols, although micronutrient availability is often limited by low solubility at alkaline pH. Careful management of P is also often needed due to sorption of P by $CaCO_3$.

33.10.8 Ecosystem Services

The term *ecosystem services* refer to ways humans benefit economically from processes and resources that are supplied by natural ecosystems for free, such as clean drinking water and pollination of crops (Withgott and Brennan, 2009). Aridisols provide many ecosystem services. Three prominent categories include *provisioning*, *regulating*, and *cultural* ecosystem services.

33.10.8.1 Provisioning Ecosystem Services of Aridisols

Grazing by livestock (mainly cattle, sheep, and goats) and wildlife is the common use of Aridisols where water is not available for irrigation. More than half of the Earth's land surface is grazed (Follett et al., 2001); most of which occurs in the dry regions (e.g., Sobecki et al., 2001). In the United States, for example, there are approximately 308 million ha of rangeland, about 31% of the total area (Havstad et al., 2007). Most vegetation on Aridisols, however, is dominated by drought-escaping annual grasses, forbs, and drought-enduring evergreen shrubs (Archibold, 1995). These have some grazing value, but less than the grazing value of Aridisols transitional to xeric or ustic soil moisture regimes, or frigid or cryic soil temperature regimes, that often have a significant component of perennial grasses. Forage on Aridisols is highly variable (Eckert et al., 1978; Schlesinger and Jones, 1984), ranging up to 10-fold differences in forage production (Ludwig, 1987). Still, huge amounts of beef have historically been generated on indigenous vegetation of Aridisols (Fredrickson et al., 1998). Overgrazing on some Aridisols has been accompanied by a drastic change in the structure of vegetation giving rise to geomorphic feedbacks, such as the formation of coppice dunes (Gile, 1966; Otterman and Gornitz, 1983; Schlesinger et al., 1990; Reid et al., 1993). In the past few decades in the United States, food production from the livestock industry using Aridisols has declined because of poor economic returns, increased regulation, an aging rural population, and increasing use of drylands for diverse purposes, such as exurban development (Havstad et al., 2007).

Medicinal plants are another provisioning service associated with Aridisols. Many desert plants, especially evergreen perennials, have evolved chemical defenses that may be prime sources of anticancer compounds (Donaldson and Cates, 2004). For example, extracts from a screen of 63 Sonoran desert plants revealed that 42% of evergreen species, 37% of woody perennials, 36% herbaceous perennials, and 23% of annuals showed greater than 50% inhibition against HeLa cells. Other potential sources of anticancer compounds are found in the rhizosphere of plant roots growing in Aridisols (He et al., 2004) and in plants with genetic variability among the populations unique to Aridisol habitat, such as *Anemopsis californica* (Medina-Holguín et al., 2007, 2008).

33.10.8.2 Regulating Ecosystem Services of Aridisols

Aridisols are important in regulating air quality at both the local and global scales. At the local scale, dust storms can reduce visibility on highways and aggravate respiratory problems in areas where Aridisols have been disturbed by construction or agriculture (e.g., Bar-Ziv and Goldberg, 1974). Globally, Aridisols are important sources of atmospheric dust that not only affect air quality, but also influence rain chemistry, ocean fertilization, and albedo (Schlesinger, 1997; Kaufman et al., 2005). The key variable linking Aridisols and air quality are ground cover in the form of desert pavement, biological soil crusts, or vascular plants. When ground cover is removed or disturbed, soil particles, especially in the very fine sand and silt fractions, are vulnerable to entrainment and movement by wind (e.g., Belnap and Gillette, 1998).

Aridisols play a similarly important role in regulating water quality. While forested mountains are the source of most water in regions with Aridisols, a significant proportion is also generated by lower elevation rangelands during infrequent and often torrential rainfall events (Havstad et al., 2007). Aridisols at lower elevations that are occupied by shrublands generally produce more runoff than those occupied by grasslands (Schlesinger et al., 2000; Wilcox and Thurow, 2006). As overland flow moves across shrublands, it carries more sediment than in grasslands. Moreover, soil moisture is more heterogeneous in shrublands than in grasslands because soil moisture is deeper beneath rills and gullies (Dick-Peddie, 1993). As with air quality, a highly disturbed landscape of Aridisols will give rise to lower quality water than neighboring nondisturbed Aridisols.

Carbon sequestration by soil is an important ecosystem service of global significance. Aridisols, however, have low contents of organic carbon, only 4% of the total, but contain the greatest amount of soil inorganic carbon (SIC, calcium carbonate), 48% of the total (Eswaran et al., 2000). Soil inorganic carbon is greatest in Aridisols because, as discussed earlier (Section 33.10.5.5), its occurrence is mainly limited to dry climates. Of the global 946 Pg of SIC, arid regions contain 77.8%, followed by semiarid regions (14.2%), Mediterranean climates (5.4%), permafrost (1.9%), humid (0.5%), and perhumid areas (0.2%) (Eswaran et al., 2000). Although the global amount of SIC is large, containing more carbon than the amount in terrestrial vegetation (560 Pg) or the atmosphere (820 Pg), the rate at which SIC forms is relatively low: 0.3–15 g $CaCO_3$ m^{-2} year^{-1} (Machette, 1985; Eghbal and Southard, 1993b; Reheis et al., 1995; Monger and Gallegos, 2000). The loss of CO_2 from SIC also appears to be low even when petrocalcic horizons are exposed at the land surface by erosion (Serna-Perez et al., 2006). However, because some SIC is linked to microbial and root precipitation, labile pools of SIC may exist, but presently remain unmeasured.

33.10.8.3 Cultural Ecosystem Services of Aridisols

Early civilizations arose on Torrifluvents and neighboring Aridisols, such as those in Sumeria in the fourth millennium

B.C. when irrigated agriculture in that arid climate encouraged stable settlements, led to surplus food, freed people to pursue specialized trades and develop social order and cultural creativity (Durant, 1935). Similar cultural developments arose in arid and semiarid climates along the Indus River of ancient India, Hoang-Ho (Yellow River) of ancient China, and in dryland climates of the western Hemisphere, such as those occupied by the Inca, Anasazi, and Hohokan cultures. Today, arid climates are well known for their archaeological preservation (e.g., Egypt) as well as other cultural ecosystem services including wildlands, solitude, recreation, esthetic experiences, and places for scientific discovery.

33.10.9 Desertification

Desertification refers to the broad set of environmental degradation processes that results in a persistent decrease in the productivity of drylands—a condition that impoverishes an estimated 1 billion people (Verstraete et al., 2009). Such degradation typically involves the loss of productive grasslands and their replacement by shrublands accompanied by erosion. In addition to erosional degradation, desertification of Aridisols also includes chemodesertification in which improper irrigation causes salt accumulation (Dregne, 1983). Desertification of grazingland Aridisols can result in the spatial distribution of plants becoming very heterogeneous (Eckert et al., 1978; Schlesinger and Jones, 1984), commonly giving rise to islands of fertility (Schlesinger et al., 1990). These islands tend to be relatively stable, resistant to erosion (Otterman and Gornitz, 1983) and often trap eolian very fine and fine sand to form coppice dunes (Gile, 1966; Reid et al., 1993). These coppice dunes can range in height from a few centimeters around the base of shrubs to 1 m or more, in which case they dominate the landscape microtopography.

Desertification involves ecogeomorphic thresholds. When these thresholds are exceeded, the system is slow to recover in large part because the soil resource has changed (Bestelmeyer et al., 2009). Forces that drive desertification are coupled environmental and human systems, such as short-term climate variability and exploitation of scarce resources in areas remote from centers of political power (Reynolds et al., 2007). Recent proposals to combat desertification involve the effort to view desertification as (1) a provider of ecosystem services, (2) a coupled human ecological system, and (3) a system that must be viewed at multiple scales in order to understand its causes and consequences (Verstraete et al., 2009).
